●Published at George Banta Co., Inc., Menasha, Wisconsin. The publication number is ISSN 0002-8282.

●THE AMERICAN ECONOMIC REVIEW including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and *Supplements*, is published by the American Economic Association and is sent to all members six times a year: March; May; June; September; semi-monthly, December.

Regular member dues for 1985, which include a subscription to both the *American Economic Review* and the *Journal of Economic Literature* are as follows:

\$35.00 if annual income is \$30,000 or less;

\$42.00 if annual income is above \$30,000, but no more than \$40,000;

\$49.00 if annual income is above \$40,000.

Nonmember subscriptions will be accepted only for both journals: Institutions (libraries, firms, etc.), \$100 a year; individuals, \$65.00. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

In countries other than the United States, add \$11.00 to the annual rates above to cover extra postage.

●Correspondence relating to the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinstaw, 1313 21st Avenue So., Suite 809, Nashville, TN 37212-2786. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

●Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

●Postmaster: Send address changes to *American Economic Review*, 1313 21st Avenue So., Suite 809, Nashville, TN 37212-2786.

# Microeconomic Efficiency and Nominal Wage Stickiness<sup>†</sup>

By CHARLES L. SCHULTZE\*

...[T]he world may have its reasons for being non-Walrasian.

Robert Solow

The vast majority of our profession share a common view on most microeconomic policy issues. But we are widely split over macroeconomic theory and policy. Our consensus on micro issues arises from a shared model of how markets work in the long run. Our division on macro issues stems from a number of reasons, the emphasis on which has shifted over the years. In recent times the main disagreement has centered on how markets perform in the short run. In particular, we cannot agree on why nominal wages are sticky on the face of aggregate demand shocks. The traditional view argues that wages are structurally sticky. The new classical macroeconomists argue that wages are fundamentally flexible. But the rational expectations of economic agents, grounded on past experience with attempts at employment-supporting monetary policy, have produced the observed wage stickiness. Introduction of a changed policy regime, based on a stable growth path for the money supply or some similar rule, would—so the argument goes—eventually change the pattern of expectations and eliminate the stickiness.

A large and rapidly expanding body of recent research on implicit contracts, principal-agent relationships, and related subjects has begun to flesh out our knowledge of why wages are sticky. Almost universally the implicit contract and related literature con-

cludes that optimal behavior implies a good deal less wage flexibility in the face of changes in the marginal revenue product of labor than would occur in the spot auction markets of the Walrasian model. But this literature deals with the stickiness of *real and relative wages* in response to shocks of various kinds. It seems to have little to say about the macroeconomic stickiness of *nominal wages*. A micro theory of real wage stickiness may help explain the difficulty of adjusting to sudden large changes in aggregate supply conditions like the two oil shocks of the 1970's. But the more familiar problems facing macroeconomic theory and policy have to do with the ability of the economy to adjust to aggregate demand shocks where nominal wage stickiness is a major barrier to successful adjustment. And here the important question is what, if anything, does the new research imply for the behavior of nominal wages? It is to this subject I want to give my attention.

A road map will be helpful. After summarizing the existing literature, the first section concentrates on *relative wage* adjustments, and argues that under optimal arrangements for the determination of wages, relative wages while not rigid will be sticky. They will adjust only gradually to relative changes in the conditions facing individual firms. The paper then argues that contrary to general opinion, relative wage stickiness necessarily produces aggregate *nominal wage* stickiness; if wages move sluggishly in response to the relative conditions facing individual firms, they will move sluggishly in response to aggregate nominal shocks. Several mechanisms that might produce a flexible wage response to nominal shocks, given sticky relative wages, are considered and rejected—various forms of indexing and rational expectations. Finally the “external” nature of the gains from nominal wage flexibility is invoked against the criticism that attributing cyclical unemployment to nominal wage stickiness implies nonrational behavior on

Lawrence, Bruce K. MacLaury, Joseph A. Pechman, George L. Perry, Robert M. Solow, and James Tobin for helpful advice and comments.

<sup>†</sup>Presidential address delivered at the ninety-seventh meeting of the American Economic Association, December 29, 1984, Dallas, Texas.

the part of employers and workers. Macroeconomic shocks will gradually overcome the relative wage stickiness and move the aggregate nominal wage level in the desired direction, but the transitional costs are large.

### I. Some Relevant Features of the Implicit Contract Literature

By now the literature on implicit contracts is so large and so diverse that I cannot do it justice in a brief summary. But it is necessary to sketch out a few elements of that research, paying particular attention to several key features that bear on the relationship between wage behavior and aggregate demand shocks.

The flexible-price, market-clearing model, in which economic agents are price takers and prompt quantity adjusters, would be a useful paradigm in a very particular kind of world. In this world labor and product markets would be characterized by a great deal of homogeneity, and so individual transactions would be carried on in very "thick" markets. There would be no reason for preserving a continuity of relationships between workers and firms, customers and suppliers, lenders and borrowers. Workers would be interchangeable; the marginal revenue product of a particular class of workers would be the same regardless of the firm to which the worker was attached. Either labor effort could be easily monitored or it would be completely proportional to labor hours paid for. And, wherever commitments had to be made for the future, expectations about the important variables entering into the decision could be drawn from fixed stochastic distributions, knowledge of which, in turn, could be derived from the recurrent nature of past events. As well as being unbiased, forecasts could significantly improve on coin-flips.

The world that we are trying to model, however, is in fact different in several fundamental ways. Most importantly, in a substantial part of the economy there are large returns to maintaining the continuity of association between workers and firms. Workers acquire nontransferable, firm-specific skills; and some of the cost of the acquisition may be paid by the firm. They

acquire knowledge about the nonwage attributes of a job through experience on that job. Continuity of association also provides firms with hard-to-come-by knowledge about the reliability and productivity of specific workers. Additional transition, search, and moving costs are incurred by workers and firms when the association is broken. Substantial bilateral monopoly rents to continuity are thus generated among firms and their experienced work force.

Risk aversion introduces another reason for continuity of association. For at least some range of possible variations in the economic environment facing a firm, it is likely to be less risk averse than its workers. But the relevant insurance contracts cannot be traded separately from employment contracts, and so continuity of association becomes a joint product with insurance. Finally, in the real world, labor time is not synonymous with performance. Monitoring worker performance or effort is costly, but the payment of higher than the "going wage" will bind workers to the firms with an incentive to avoid shirking. And the particular workers who "survive" the monitoring are those who have found the premium sufficient to avoid monitorable shirking, a piece of valuable information to the firm flowing from continuity of association.

Realizing the benefits from long-term worker-firm relationships requires, of course, some sort of explicit or implicit agreement between employers and workers on the terms of the relationship, especially with respect to wages and employment opportunities. Several problems in modeling these long-term worker-firm agreements have dominated the recent literature. *First*, when the marginal revenue product of labor changes, how are wages and employment to be adjusted while still preserving contractual relationships? *Second*, since firms are much better able than workers to observe the marginal product of labor and since contingent contracts directly tied to the various states of nature cannot practically be designed, how can contract terms allow for some flexibility in meeting changing conditions without giving employers incentives to provide false information about labor's marginal product? This is the problem of

*asymmetric information* and has given rise to the modeling of incentive-compatible contracts. *Third*, since explicit written contracts between unions and employers cover only a small part of the workers involved in long-term relationships, what keeps either workers or firms from violating the implicit agreement or exploiting their half of bilateral monopoly situations when conditions are favorable to do so? Analysis of this issue has given rise to the concept of a firm's labor market "reputation," or brand-name capital, fear of losing which provides an enforcement constraint. This is the problem of *enforcement*.

Three major strands of the literature on implicit contracts can be discerned, each of which emphasizes one of the rationales for the continuity of association (without necessarily denying the existence of other aspects), and each of which deals somewhat differently with the problems cited in the prior paragraph.<sup>1</sup> The earliest version of implicit contracts emphasized the role of *risk aversion*, firms being either risk neutral or less risk averse than workers to fluctuations in their income.<sup>2</sup> Firms thus offer risk-sharing contracts that improve social welfare relative to spot auction markets. Another body of research stresses *transactions costs* and *asset specificity*—that is, the acquisition of firm-specific skills by workers, and specific and valuable knowledge about each other by both firms and workers.<sup>3</sup> This approach also emphasizes the *asymmetry* of knowledge between firms and workers about the marginal revenue product of labor, and its influence on the nature of the contract. Still a different emphasis is given in the *efficiency wage*<sup>4</sup>

literature to an assumed positive correlation between the level (or the career profile) of wages on the one hand and the "effort" or productivity of workers on the other.<sup>5</sup>

While there are substantial differences among these various approaches, they all conclude that, under optimal contracts, real wages will be smoothed in the face of changes in the marginal revenue product of labor relative to what would be predicted by an auction market. And all of them provide a rationale for the existence of *ex post* Pareto inefficiency and involuntary unemployment.

## II. Some Extensions to Implicit Contract Theory

We can distinguish several categories and subcategories of changes in economic circumstances, the wage response to which must be accommodated by social conventions and informal understandings that we call implicit contracts. Let us consider first some of the implications of contract theory as it deals with the response of wages to changes in the *relative* conditions facing individual firms or labor markets. For that purpose I define relative changes to be those which occur on the assumption that the perceived general level of opportunities facing workers—call it  $\bar{W}$ —remains unchanged in real and nominal terms. (The relevant  $\bar{W}$  is, of course, in real terms. But since we are here abstracting from any aggregate disturbances, real and nominal  $\bar{W}$  are the same.) In turn there are two kinds of relative changes in economic conditions that implicit contracts must allow for; changes which are realizations of a probability distribution known at the time the contract is entered, and those stemming from developments to which no basis could be found for assigning probabilities.

<sup>1</sup>I take the threefold categorization from the summary of wage contracting literature by Robert Flanagan (1984). See also Costas Azariadis and Joseph Stiglitz (1983).

<sup>2</sup>See Martin Baily (1974), Azariadis (1975), Donald Gordon (1974), Sanford Grossman and Oliver Hart (1981) and Bengt Holmstrom (1983).

<sup>3</sup>See Benjamin Klein (1984), Klein, Robert Crawford, and Armen Alchian (1978), David Mayer and Richard Thaler (1979), Michael Wachter and Oliver Williamson (1978).

<sup>4</sup>See Carl Shapiro and Stiglitz (1984), Edward Lazear (1981), and Janet Yellen (1984).

<sup>5</sup>In some of the efficiency wage models, the firm attempts to pay more than the going wage, creating a penalty for workers who shirk and are fired. When all firms do this, aggregate unemployment is created and a shirking penalty still exists. No implicit contracts are needed. Both Victor Goldberg (1982) and Lazear, however, postulate a positively shaped earnings profile (new workers earn less than their marginal product) as a way of getting employees to post a performance bond thereby creating shirking penalties. This version does require implicit contracts enforced on the firm by fear of reputation loss.

To deal with implicit labor contracts covering the long tenures that are typical in U.S. industry, it is necessary to make the currently out-of-fashion distinction between risk and uncertainty. Most of the mathematical modeling of implicit contracts has assumed that workers and firms base their agreements on a *known* probability distribution (presumably commonly held) of the relevant variables, most importantly the marginal revenue product of labor or some related variable. The distribution of the mean expected bilateral monopoly rents from continuity is decided at the beginning of the contract on the basis of the known distribution of possible economic environments that will be faced over the life of the contract, and the contract then specifies the behavior of wages (and in some cases employment) as the realization of that distribution occurs. The wage is either rigid or changes sluggishly in the face of these changing realizations. But recent research on the surprisingly long lengths of job tenure in the United States casts doubt on the usefulness and sufficiency of this assumption. Robert Hall (1980) has estimated that, in 1973, half of all work in America was done on jobs whose completed tenures were fifteen years or more. And for men alone the relevant completed job tenure was twenty-five years! Douglas Wolf and Frank Levy (1984) reached very similar conclusions on the basis of a 1979 survey. The contracts, rules-of-behavior, and social conventions that make possible such long associations must be such as to allow wages to adjust appropriately in response to changes in circumstances whose probability of occurrence could not be determined in advance. In other words, the informal agreements which make possible long-term association between workers and employers must take into account Knightian uncertainty about future possible outcomes. With respect to many of possible states of the world, over such a long period of time, there is no basis in past statistical regularities for knowing the distribution. As William Nordhaus (1976) points out, contracts must take account of changes in the economic climate (i.e., when the parameters of the distribution shift) as well as changes in the economic weather (i.e., as realizations of the known distribution).

Most of the possible long-term changes to be faced by firms and workers do not result from the cyclical variance of aggregates, like national income and output, but from changes in relative variables potentially responding to a bewildering permutation of possibilities. Seen in 1973, what were the rationally expected probabilities of the 1974 and 1979 oil price increases, the introduction and growth of personal computers, or the Chrysler brush with bankruptcy? Compared to workers, firms may indeed be relatively risk neutral to temporary changes in income following some known distribution. But no firm is so risk neutral and has such unlimited access to capital as to enter upon or honor contracts specifying rigid wages or some fixed function of wages on employment over very long periods,<sup>6</sup> when no rational basis exists for specifying the distribution of outcomes. Some of the modern wage literature (for example, Hall and David Lilien, 1979; Sanford Grossman and Oliver Hart, 1981) models a contract with a "lump-sum" distribution of the rents—that is, an amount to be paid the workers regardless of unemployment status—and a marginal compensation, paid when the worker is employed and itself an agreed upon increasing function of the level of labor input. Employers then determine employment by maximizing profits in the light of the marginal compensation schedule. In these approaches, the climatic changes to which I refer would be an occasion for changing the basic lump sum distribution of the rents.

A workable distinction can thus be made between those contract provisions which deal with wages in the face of moderate and temporary changes in the marginal product of labor that are perceived as the realization of a known probability distribution and those provisions which deal with climatic and permanent changes, the probability of whose

<sup>6</sup>Indeed, for contracts covering long periods of time, workers are probably less risk averse than firms. Under some range of unfavorable outcomes, rigid wages could mean bankruptcy for the firm. Against relative changes in fortunes the worker loses only his "rent" from continuity plus search costs. And, however well stockholders may be able to diversify against bankruptcies, the managers of the firm find it much more difficult.

occurrence cannot be estimated before the fact. With respect to changes in labor demand that are perceived to be consistent with a previously known distribution, implicit contract theory predicts either rigid wages or—in the models like those of Hall and Lilien and Grossman and Hart—wages which move less than spot auction markets would predict but are positively correlated with the level of employment. But the informal agreements or generally accepted conventions that we call implicit contracts must also provide for changes in circumstances whose probability cannot rationally be estimated at the time workers enter into the contract. These climatic changes in economic circumstances can be of several broad kinds. They might involve a relatively long-term change, because of shifts in demand or costs, in the rents available to be shared by a firm and its workers. Long-term changes in the relative demand and supply of particular occupations or in particular local labor markets will also call for changes in relative wages around a given  $\bar{W}$ .

If the present value of the stream of benefits to workers (wages and employment probabilities) flowing from continuing with the firm begins to decline relative to the alternative combination of initial investment costs and future rents that can be generated at other firms, it is appropriate that contract terms signal the information to workers, so that they can make the relevant comparisons, and decide whether to quit the firm. Similarly, if a substantial and permanent decline occurs in the relative demand for labor by occupation or locality, wages ought to signal the change. Conversely, economic circumstances might increase the rents to be divided making it optimal for the firm to enlarge its share of the relevant labor market pool of experienced workers. In that case, the signal of higher relative wages ought to be transmitted to attract from other firms or occupations workers for whom the lost rents are less than the improved opportunities.

An efficient determination of wages must thus cope with two hard-to-reconcile sets of facts. Because long continuity of association between firms and specific workers confers substantial benefits on both parties, rent-sharing arrangements that offer protection

against exploitation and promote such continuity are profitable. But the period of association is so long that the probability distribution of circumstances requiring changes in wages is largely unknowable. And so the rules and conventions governing wage determination must be flexible enough to allow response. Seen in this light, the terms "implicit contract" may be misleading. It is, I think, useful to think of wages as being set and periodically revised by firms within limits imposed by a set of social conventions, concepts of equity and fairness, and informal understandings. These conventions, concepts, and understandings provide substantial, if imperfect, protection against exploitation but allow flexibility to deal with Knightian uncertainty.

While very lengthy association requires relative wage adjustments in response to "unforeseeable" changes in circumstances, other characteristics of the labor market suggest that those adjustments will tend to be gradual and delayed. It would be hard to account for the long job tenures that we observe unless the combination of positive returns to association and the cost of transition were quite sizeable. The quantitative evidence on the magnitude of explicit turnover costs suggests that they are large. Daniel Mitchell and Larry Kimbell (1982), for example, report a recent estimate, based on a survey of Los Angeles firms, that firms' own costs of turnover (exit costs plus replacement costs) averaged \$3,600, \$2,300, and \$10,400 for production, clerical, and salary-exempt workers, respectively.

Under these circumstances, erroneous signals can have asymmetrical results. Changes in wages undertaken on the mistaken identification of a temporary change in circumstances as a permanent change can cause a substantial loss to workers and firms from the unnecessary scrapping of "investment" and the incurring of other turnover costs. Entire rent streams are wiped out to the extent that workers having transferred to other firms cannot return when the mistake is discovered. Moreover, once experienced workers do change jobs, it is likely to take several tries before they find another long-tenure job. Hall (1982), for example, shows that in 1978 a worker aged 45–49 *who was in*

a new job had only a 20 percent probability of holding that job as long as five years.

While the large magnitude of rents for experienced workers tends to provide some room for errors, workers are presumably arranged along a spectrum with respect to their own evaluation of potential opportunities elsewhere. As a consequence, the losses from the errors will be a continuous positive function of the size of the errors. Errors of the opposite type—failing to introduce a contract change to meet a permanent alteration in the climate—can be reversed at a much smaller cost. Some workers will have remained too long with a particular firm, while a smaller group will have lost income from the higher layoffs associated with this type of error. But these losses are likely to be much smaller than the loss of the rent stream itself, unless the error persists for a long time.

Thus, given Knightian uncertainty about economic conditions over the long length of job tenures, implicit contracts must allow for the possibility of relative wage changes in the face of climatic changes in external conditions. But the interest of both firms and workers dictates that those changes occur only after enough information has been accumulated to warrant a high probability forecast that the change is permanent. To justify a substantial wage adjustment, it is not sufficient that the firm act on unbiased forecasts—they must also acquire some confidence in the accuracy of the forecasts.

One might object to this line of reasoning on grounds that failure to adjust wages quickly enough while the evidence is accumulating that the change in circumstances is permanent, is itself likely to send out wrong signals. If, for example, wages are slow to adjust downward when the demand for labor falls, employment will decline. Why will workers not take this as a signal that the future stream of benefits from staying in the current job have declined relative to earlier anticipation? There are a number of reasons why this objection is not valid. First, a change in wages is known immediately, while it takes some time to begin to realize that an actual change in employment reflects a shift in the long-term distribution of employment prob-

abilities. Second, the common practice of layoffs subject to recall is a way for a firm to signal that the lower employment is expected to be temporary. Third, significant downward changes in relative wages are not lightly made. Given the inability of workers easily to assess the magnitude of the available rents, firms are deterred from exploiting the bilateral monopoly relationship through the damage they might do to their "reputations" and the future increases in employment costs thereby imposed. Since reputation is a fragile asset, and since workers are naturally less likely than firms to interpret current facts as warranting a relative wage cut, firms must wait until a substantial body of evidence points in the required direction. The efficiency wage literature emphasizes the unfavorable productivity consequences of relative wage reductions that turn out to be unwarranted. And, since firms know that it is difficult to reduce wages once they have been raised, they do not want to make a mistake in the upward direction. As a consequence, wage changes that survive these barriers are much more clearly interpreted as a signal that the stream of future rents has changed than are variations in employment.

Efficient implicit wage contracts, in the presence of uncertainty, must also have the characteristic that they minimize "haggling costs." They should not lead to a constantly renewed battle over the division of the rents. Frequent struggles would waste resources, possibly reduce productivity, and erode scarce reputation capital, thereby reducing the probability of long-tenure associations. These considerations argue that significant relative wage adjustments to meet perceived permanent changes in condition be an infrequent occurrence and not lightly changed once made.

In sum, modern contract theory concludes that relative wages will tend to be quite sticky in comparison to predictions from the auction market model, in the face of changes in conditions that are the realizations of known probability distributions—what I have loosely called temporary changes. But the existence of very lengthy job tenures and the large gains from continuity suggest that the social conventions and informal agree-

ments which we call implicit contracts must provide for adjustments in wages that move towards market clearing in response to unforeseeable permanent changes in relative economic conditions. Finally, however, the substantial penalties which can be suffered if firms and workers respond to erroneous signals by prematurely severing association call for informal arrangements and agreements that produce a very slow and cautious adjustment of wages even to what ultimately turn out to be permanent changes in relative conditions.<sup>7</sup>

It is not surprising, given the large social returns to continuity of association and the very great difficulty of distinguishing temporary from permanent changes in economic circumstances, that society should have developed social conventions and informal agreements that minimize the sending of premature signals for a reallocation of resources.

### III. Response to Aggregate Demand Shocks

So far we have considered a world in which only relative or local changes are permitted, a world in which the nominal and real value of the general wage level, or the wage "norm," was fixed. Now impose aggregate demand shocks on such a world, optimal adjustment to which requires a change in the path of average prices and

wages. (For simplicity of exposition we will be considering only aggregate demand shocks, and exclude aggregate shocks to the supply curve, like those arising from OPEC-imposed oil price increases or from crop shortages. We can thus assume that the equilibrium solution will not call for changes in aggregate real wages.) An efficient system of implicit contracts must obviously provide for adjustments in the nominal wages of individual firms when changes occur in the average level of nominal wages,  $\bar{W}$ . Under the social conventions and understandings which govern wage determination, there is a rebuttable presumption that—barring the existence of circumstances which call for changes in real and relative wages—nominal wages in each firm will be adjusted in line with observed changes in prices and wages generally. But this process of wage determination does not generate prompt and flexible adjustment of aggregate nominal wages to nominal shocks. A change in the average level of wages is the product of changes in wages by individual firms. To the extent that individual wage adjustments must wait on changes in the average, aggregate nominal wage flexibility will *not* be a characteristic of the system. And, as discussed below, this is also true, but to a somewhat lesser degree, of the wage response to price changes. Given the substantial costs of sticky nominal wages to society as a whole and to individual firms and their workers, is there not some other adjustment mechanism which would generate a prompt and flexible nominal wage response, preserving relative wages but producing the desired nominal flexibility?

Several lines of inquiry suggest themselves. *First*, why are not nominal wages explicitly indexed to some aggregate nominal indicator, producing the appropriate change in  $\bar{W}$  in response to aggregate demand shocks? *Second*, even with relative wage stickiness, would not rational firms and their workers forecast the ultimate equilibrium change in  $\bar{W}$  and promptly set individual wages accordingly? And, *finally*, if that is not feasible, why do implicit contracts not permit swifter and larger nominal wage adjustments by individual firms under the force of aggregate nominal shocks?

<sup>7</sup>Ian McDonald and Solow (1981) have examined union wage bargaining, in which the bargain determines both employment (for example, via work rules) and wages. They assume symmetric information and show that under a number of different bargaining conventions—including one which preserves for the parties "fair shares" in net revenues—shocks to the firm's demand curves may produce small or zero change in wages, so long as  $\bar{W}$  is constant. Some strands of implicit contract literature also model the contracts as specifying certain aspects of the employment decision. Employers do tend to hoard labor during downturns. The implicit contract can thus be viewed as specifying a wage and, for a known distribution of future conditions, a probability of suffering unemployment. Applying the McDonald-Solow analysis to this arrangement, one could conclude that even unforeseen "climatic" changes in circumstances facing the firm would more likely result in a change in the unemployment probability than in the wage.

Let us start with the issue of indexing wages in individual firms to the general price level. In the United States, wages are not widely protected against changes in price by explicit indexing formulae. In 1983, only 58 percent of union workers were covered by COLAs. On the average, the ones that were, received protection against only 53 percent of the changes in the *CPI*. Jo Anna Gray (1978) and Stanley Fischer (1977) examined the conditions under which indexing would or would not be optimal for individual firms given the assumption that wages once set are not renegotiated for some period. The main conclusion from this research is that, in the face of real (as opposed to nominal) shocks, indexing, by freezing real wages, produces real wage results that are not optimal for the firm. Given the probability that nominal and real shocks are both likely to occur, Gray shows that *partial* indexing will be an optimal choice. Moreover, even nominal shocks are likely, during the transition to a new equilibrium, to have nonneutral effects; the firm's product price and the Consumer Price Index may not move in parallel. As a consequence, indexing would have unwanted real effects even in the face of monetary shocks. While we have seen that some degree of real wage stickiness is optimal, the absence of full indexing even in multiyear union contracts indicates that the opposite extreme—automatic guarantees of a fixed real wage over several years—is not a workable approach.

Within-year indexing is virtually nonexistent in annual union contracts and in the annual wage adjustment cycle followed by the vast bulk of nonunion firms. Under implicit contracts, changes in the path of average wages and prices in the economy as a whole or in relevant submarkets are commonly agreed to constitute a major element in determining the size of those annual wage adjustments. But, in the United States, it is almost universally the practice not to make the relationship to the price level or to average wages an explicit and automatic one, either within the year or over longer periods. And, as noted earlier, in those multiyear union contracts where indexing is found, that indexing is almost always less than complete. Haggling costs are apparently minimized by

making periodic wage adjustments that simultaneously take into account nominal, real, and relative factors, rather than by fixing the nominal relationship in a formula and separately adjusting for changes in real and relative conditions.

In any event, even if wages were fully indexed to prices, they would not produce highly flexible nominal wages in response to aggregate demand shocks. The cumulative costs of wage indexing, in the face of real shocks and the transitional nonneutrality of nominal shocks, would be severely exacerbated if the indexing were instantaneous. As a consequence, the indexing we do observe—except in countries which have developed extremely rapid and sustained inflation—typically involves a substantial lag between observed price changes and wage adjustments. Such indexing only guarantees a gradual response of wages to aggregate demand shocks in proportion as prices themselves are flexible in the face of constant wages. Even if prices were competitively determined, the economy would still have to work its way through a series of price-wage-price reactions in each one of which prices fell, relative to wages, by an amount depending on the slope of the marginal cost curves. And prices do not move with such frequency or flexibility. Arthur Okun (1981) has carefully elaborated the reasons why, in the customer markets which predominate in modern economies, prices are not likely to move quickly and easily up and down a marginal cost curve. Robert Gordon (1981) has elaborated how the highly articulated input-output relationships of modern economies tend to slow the price reaction to aggregate demand shocks. And George Akerlof and Janet Yellen (1984) have recently shown that in less than perfectly competitive markets inertial price-setting behavior in response to a shock may impose only second-order losses on the firms who follow such behavior, even though the macro result may be first-order losses for the economy.<sup>8</sup> Everything else

<sup>8</sup>Technically the Akerlof-Yellen proposition applies to situations in which agents' objective functions are differentiable in their own prices and wages—a condition that is not met in the competitive model, but is met in a wide range of other market models.

being equal, indexing wages to prices would provide some nominal wage flexibility in the face of nominal shocks. But if wages are otherwise sticky, indexing them to prices would still yield a very gradual iterative process of demand inflation or disinflation.

Granted the obstacles to indexing wages to prices in implicit contracts, and the insufficiency of that arrangement—even if feasible—to produce prompt nominal wage adjustments, why are not implicit contracts indexed to some aggregate like nominal *GNP* or the money supply? Such an arrangement might seem to be a way to approximate the role of the Walrasian auctioneer, automatically generating  $\bar{W}$  at a level to clear the aggregate supply-demand balance, while relative wages continued to be set under implicit contracts along lines suggested earlier. In fact, of course, we observe no such arrangement anywhere in the world, and a little thought supplies a number of reasons. For purposes of indexing wage contracts to nominal *GNP*, some agreed-upon process would have to be found for separating “disturbances” in nominal *GNP* from the trend increases consistent with full employment at a stable inflation rate. Anything that altered the parallel growth of average and marginal labor productivity, or the growth of full employment labor inputs, would change the trend and require the contracts to be renegotiated. Robert Gordon (1981, 1983) has identified a number of reasons, why, even if the appropriate split could be made between trend and disturbances, indexing wages to nominal *GNP* would not be feasible in implicit contracts. If prices themselves are not completely flexible relative to wages, declines in nominal *GNP* under an indexed system would produce long periods with unwarranted real wage decreases. And, since the costs and hence the prices of the typical large firm depend on the costs and prices of a long and heterogeneous chain of suppliers, indexing wages on nominal *GNP* would only index part of an individual firm’s costs. Workers would rightly be skeptical that such an indexing system would quickly move prices down proportionally with wages.

The problems of automatic indexing to some other nominal aggregate, like the mon-

ey supply, are even worse since the relationship between any other aggregate variable and the equilibrium full employment wage level is still more complex and unstable than it is in the case of nominal *GNP*. And unless all firms could somehow agree on a common translation formula for indexing purposes, nominal demand shocks would produce a wide dispersion of unwarranted changes in relative wages. (This point is elaborated further in the paragraphs that follow.) More complex explicit indexing formulas can be imagined, but are no more feasible than simple ones. The two parties to a contract would be subjecting themselves to very great uncertainty in agreeing to a given information set and forecasting model as the basis for the indexing. It takes a very large run of data to sort systematic error from noise in economic time-series. And so agents would have huge space for disagreement about the appropriate information set and the relevant model for translating information into forecasts. Alternative choices could lead to biased outcomes, whose bias could not be determined for a very long time. (The appropriate order in which to enter variables in a vector autoregression model is hardly the subject for fruitful labor negotiations.) In short, feasible state-contingent contracts cannot be designed to replace the Walrasian auctioneer as a means of coordinating the system’s response to nominal shocks.<sup>9</sup>

In the absence of explicit state-contingent contracts, can nominal wage flexibility be rescued by a rational expectations model of wage determination? Why do not individual firms and their workers rationally forecast the change in the equilibrium path of average wages ( $\bar{W}$ ) expected to result from a nominal shock, and promptly change wages accordingly, recognizing that their actions involve no decision to change relative wages?

<sup>9</sup>Under extreme circumstances the parties may introduce such contacts. In the German hyper-inflation of 1923, the pace of inflation became so swift that weekly wages were finally indexed to the prices *expected* to prevail in the subsequent days when the wages would be spent. An *ex post* adjustment was then made to correct for errors in the forecast. A similar arrangement was adopted during the Polish hyper-inflation of the same period.

Stochastic errors in forecasting could generate temporary wage "errors" and departures of employment from its natural rate. But nominal wages would fundamentally be flexible.

A rational expectations approach to the determination of the aggregate nominal wage and price level, however, cannot simply be carried over into a world of sticky *relative* wages. There are several reasons why this is so. In the first place, in the new classical model it is *not* the expectational element that generates aggregate nominal wage flexibility. Rather, a prompt response of aggregate nominal wages to nominal shocks is guaranteed by the perfect *ex ante* flexibility of relative wages in auction markets. In these models a downward nominal demand shock generates a prompt and "neutral" change in the path of nominal wages precisely because of individual workers' presumed willingness to underbid wages, shading their bids and offers in the face of excess supplies, to the point where markets are cleared. In the auction-market model, workers or groups of workers are willing to accept lower wages in the face of excess supply even when errors in expectations lead them to misperceive the entire wage cut as a relative one. In the event of such misperceptions, some labor supply is withdrawn but nominal wages still fall. And as soon as the misperception is corrected, wages quickly fall by the remaining amount necessary to eliminate excess labor supply and clear labor markets. In the world of implicit contracts I have described earlier, however, the absence of substantial relative wage flexibility eliminates this basis for prompt nominal wage flexibility.

In the absence of auction markets with their relative wage flexibility, the achievement of aggregate nominal wage flexibility becomes a prisoner's dilemma problem. But, since wages are not completely rigid under implicit contracts, it is not possible that individual firms and their workers forecast the ultimate equilibrium response of average wages to nominal shocks, promptly adjust their own wages to it and thereby solve the prisoner's dilemma in favor of nominal wage flexibility? I think not. Two key features of

implicit contracts interact with one central feature of rational forecasts to reduce sharply the feasibility of commonly shared expectations about the equilibrium  $\bar{W}$  as a surrogate for Arrow-Debreu contingent claims contracts. *First*, firms are wage setters, not wage takers; *second*, frequent haggling over wage changes is very costly to the development of mutually beneficial long-term relationships between workers and firms; and *third*, forecasts of equilibrium wage and price levels are subject to substantial stochastic error and forecast outcomes are likely to be widely distributed over the population of wage-setting firms.

In a world of auction markets, the fact that forecasts of individual agents are widely distributed around the "true" mean is for most purposes irrelevant. In his seminal article (1961), John Muth pointed out that cross-sectional differences in expectations posed no problem for the theory because their aggregate effect would be negligible so long as deviations from the rational forecast by individual firms were not strongly correlated with each other. In auction markets, specific prices or wages are not determined by individual forecasts. But, in a world of implicit contracts with firms as wage setters, they would be. The dispersion of individual forecasts concerning the equilibrium nominal wage  $\bar{W}$ , and therefore the dispersion of individual wage decisions, would often be a wide one. Robert Lucas' words about the role of rational expectations in shaping the actions of economic agents are relevant in this regard:

Neither will [rational expectations] be applicable in situations in which one cannot guess which, if any, observable frequencies are relevant: situations which Knight called 'uncertainty'. It will most likely be useful in situations in which the probabilities of interest concern a fairly well defined recurrent event, situations of 'risk' in Knight's terminology. [1977, p. 15]

Changes in the path of nominal wages, however, have not simply, or even primarily, been driven by recurrent patterns of endoge-

nous events, at least in recent years. The Vietnam War, two massive oil shocks, the introduction of floating exchange rates, and the institution of a new monetary regime in the United States in 1979 have dominated events. Even if the vast majority of firms held a broadly similar view of the way the economic world works, the very great macro-economic uncertainty and the stochastic variance of prior forecasts around the actual outcomes would guarantee a wide dispersion of individual forecasts whenever large shocks occurred.

A wide dispersion of the forecasts of individual economic agents and the experience of errors in prior forecasts would have a number of consequences. In the first place, given the large room for disagreements about the forecast, we have to rule out on moral hazard grounds implicit contracts under which workers, prior to actually observing a deterioration in employment conditions, would accept employer forecasts of a declining equilibrium nominal wage as the basis for a downward wage adjustment. But even waiving this difficulty, the large dispersion of individual forecasts would result in widespread unintended relative wage changes, even if all firms and their workers accepted a wage adjustment based on the firm's equilibrium forecasts. Because of both risk aversion and the consequences to firms and workers that follow from erroneous signals, these changes could impose significant losses on the parties. Yet, a high frequency of wage changes is also costly, so that errors would tend to persist for some time. Indeed, given the incompleteness and imperfections of current information, and the murkiness of the variable being forecast—the equilibrium nominal wage level—there would be substantial room for disagreement among the parties as to whether or not a prior forecast had or had not been in error. Finally, to the extent that “bad” experience with forecasts caused some firms and workers to reduce the forward-looking element in wage setting, the unreliability of forecasts for those who used them would become greater. It would become increasingly less rational to base individual wage decisions on the assumption that

others were forecasting the equilibrium adjustment and promptly adjusting wages accordingly. Thus, without the “policing” mechanism of *relative* wage flexibility, a system that relied on rational expectations forecasts of the equilibrium wage outcome would be unstable.

In sum, under implicit contracts, widespread tying of individual wage decisions to expectations about equilibrium aggregate wage outcomes is not a feasible way of anticipating the optimal adjustment to nominal shocks. The policing mechanism of *ex ante* relative wage flexibility is absent, so that nominal wage flexibility becomes a prisoner's dilemma problem. And prompt rational expectations “indexing” to the equilibrium outcome is no solution to that problem, since it would increase haggling costs, produce unwanted relative wage changes, and become increasingly an irrational action on the part of individual firms.

In the absence of widespread indexing to some nominal aggregate, or to the rational expectation of the equilibrium wage norm  $\bar{W}$ , wages must find their way to a lower level as the product of specific decisions among individual firms and their workers, in a process constrained by the same social conventions and informal agreements that dictate the change in relative wages under implicit contracts. In a world of price and wage setters, firms and workers observe demand shocks principally in the form of changes in their own physical quantities—sales first and then output and employment—and in the context, initially, of an unchanged perceived level of  $\bar{W}$ . The dynamics of the process by which firms adjust from one level of the work force to another can, as described by Okun and by George Perry (1980), generate modest wage changes in response to the aggregate shocks. Beyond this, the change in external pressures for wage adjustment must be large enough and last long enough to satisfy the constraints imposed by long-term implicit contracts on “permanent” wage changes. Finally, to the extent that these changes become substantial and widespread, enough to yield a long-term change in the perceived level of  $\bar{W}$ , the whole nominal

wage structure around which individual adjustments occur will be changed.

There are several points to note about this process. The major gains, in terms of higher employment, that came from lowering wages in the face of downward aggregate demand shocks do not accrue to particular workers in particular firms as the result of their own actions. Rather, the gains accrue through the effect of generalized lower wages in reducing prices, raising real money balances and thereby increasing aggregate demand. Once the assumption of flexible auction markets and a competitive bidding down of wages by individual workers is abandoned, it is no longer valid to level against sticky-wage theories the charge that they imply an irrational failure on the part of economic agents to pursue unexploited gains from trade. Without the Walrasian auctioneer, the individual firms in an economy are, as noted earlier, in a prisoner's dilemma. The large comparative statics gain from an aggregate nominal wage cut does not translate into such a gain seen from the point of view of individual firms.<sup>10</sup> The potential gain they see is the one that would accrue from making a relative change. They will indeed make such changes, but slowly and cautiously, acting under the constraints on relative changes spelled out earlier.<sup>11</sup> Only as the perceived long-term level of  $\bar{W}$  falls will the situation be different.

<sup>10</sup>In his 1977 article, Robert Barro decouples the nominal wage and employment responses to perceived nominal shocks. He argues that even if nominal wages are sticky, optimal contracts would call for the maintenance of employment. Firms would vary prices to achieve this result despite the stickiness of nominal wages. Otherwise, says Barro, the parties would be ignoring the unexploited gains from trade, an irrational act. This paper is not principally concerned with price behavior. But it is clear that the same externality argument, set forth above with respect to wages, holds for prices. Without auction markets or some surrogate for the Walrasian auctioneer, the external nature of the gains from price changes would tend to negate the force of the Barro argument.

<sup>11</sup>Since the macroeconomic effects of their own wage and price decisions do not enter into economic agents' objective functions, the Akerlof-Yellen conclusions about the small size of losses from "near-rational" behavior would apply to the nonauction markets I am here describing.

Since what is important for nominal wage adjustment is the *perceived* level of  $\bar{W}$ , expectations about its future value will, of course, be relevant. Within the constraints imposed by implicit contracts, wages in individual firms have to be adjusted to deal with changing conditions. Since wage changes are difficult and impose strains on long-term relationships, the wage once set has to last for a while, typically at least a year (and under union contracts often longer). The expectations that workers and employers have about the future course of average wages and prices will therefore exert an important influence over the current wage decision. I do not want here to join the controversy over the extent to which wage setting is backward or forward looking. But what is central to my message is that the relevant forecast does not assume prompt adjustment to a new equilibrium wage but rather the more hesitant and gradual process described above.

The appropriate framework for analyzing the aggregate behavior of wages, therefore, is *not* one in which certain macroeconomic imperfections—information gaps or misperceptions about the general wage and price level—prevent the market-clearing adjustment of wages, which themselves are perfectly flexible in the face of relative disturbances. The essence of the behavior of wages in response to aggregate demand shocks is just the opposite. Macroeconomic shocks break through the short-run stickiness of wages and prices in the face of relative disturbances to produce the aggregate adjustments, albeit slow and gradual ones, that we do in fact observe.

There is a nice paradox in all of this. A prompt adjustment of nominal wages to aggregate demand shocks, leaving relative wages unchanged, can be produced only by a system of highly flexible relative wages. Conversely, the existence of sticky relative wages yields long transitional periods in which firms are adjusting individually to nominal shocks, and produces, as a side effect, changes in relative wage and prices.

#### IV. Final Reflections

The large costs which accompany disinflation arise from the fact that society has to

send out the same kind of initial signals—changes in the volume of sales—when it wants a reallocation of resources as it does when it wants a change in the general level of wages and prices. In the first situation, given the substantial efficiencies which flow from long-term associations of suppliers with customers and firms with workers, very cautious and sluggish changes in wages and prices are the optimal response to signals. A large part of the adjustment is optimally taken up as temporary variations in slack—adjustments in hours, layoffs and rehires, inventory building and depletion, and rationing of various kinds. Indeed, a large part of economic life is dominated by the social conventions, institutions, and patterns of behavior that have evolved to avoid the chaos and inefficiencies that would result from continuous market clearing.

The signals which firms initially receive when aggregate demand shocks occur are the same as those for a resource transfer, but an exactly opposite response is wanted—large changes in wages and prices and small changes in quantities or slack. Since the bulk of the disturbances to which individual firms and workers must adjust are relative or local in nature, and since over long periods of time micro efficiency tends to outweigh aggregate resource utilization as a source of economic welfare, wage- and price-setting institutions have developed with a bias toward the sluggish response called for by considerations of micro efficiency. The cyclical behavior of the aggregate wage and price levels unfolds from the gradual overcoming of that bias.

In the long run, those features of economic relationships which make short-run price and wage stickiness optimal and which rationally prevent continuous market clearing disappear. Specific assets are converted to capital. Attrition and learning change the mix of skills. Random changes get smaller compared to systematic changes. The private returns from specific customer-supplier and worker-firm attachment shrink relative to the returns from making appropriate adjustments to changes in tastes, technology, and other external developments. The rationally based barriers to market clearing crumble.

We economists are indeed correct to insist on the long-run efficacy of markets and the utility of the market clearing paradigm as a way of explaining long-term market allocations. But we need not abandon the premise of the rational maximizing calculus in order to explain the structural stickiness of wages and prices and the failure of markets to clear in the short run. Both phenomena—long-run market clearing and short-run stickiness—ultimately derive from the same rational aspects of human behavior.

Some of the consequences of this recognition are nevertheless very troubling for economic theory and theoretically informed empirical research. In the new classical economics, there is no need for empirical research to determine how wages and prices respond to demand shocks, *given* expectations about the general price level. Pure theory—the auction-market model—dictates how prices and wages behave. Empirical research is needed principally to tell us something about the formation of expectations on the general price level.

While contract theory and related research has been developing rationally based foundations for structural wage and price stickiness, the work to date is essentially in the form of existence theorems. That is, it tells us *why* sticky wages are consistent with the rational calculus. But it does not give us a theoretical basis for specifying the two basic components of macro wage adjustment: What “laws” do firms follow, under implicit contracts, in adjusting their wages, assuming the stability of  $\bar{W}$ , the wage norm? And what does it take to produce a perceived “permanent” change in that norm?

A full and complete microeconomic foundation to wage adjustment with the power of the auction-market model may never be forthcoming. If that is so, we may have to look to regularities derived from macroeconomic empirical research to infer microeconomic behavior. But this raises another set of problems. While forward-looking expectations play much less of a role in the macro wage adjustment process I have outlined, they are not completely absent in forming perceptions about the wage norm. Hence the force of the Lucas critique, though weakened,

does not disappear. The new classical economics simply assumes that structural behavior is market clearing, and hence claims to be able to identify the expectational effects of a particular policy regime. In the absence of such an a priori assumption, however, how does one go about separately identifying the expectational from the structural elements in wage formation? I do not have the answer. Conceivably, economics, like physics, is subject to a fundamental indeterminacy theorem.

# The Production Process in a Competitive Economy: Walrasian, Neo-Hobbesian, and Marxian Models

By SAMUEL BOWLES\*

Recent years have witnessed a growing interest in the internal organization of the firm. Many, taking the work of Ronald Coase (1937) as their starting point, have developed insights based on the concept of transactions costs. Others, building on the work of J. R. Commons (1918, 1935), have developed an historical and institutional analysis of the structure of collective bargaining and internal labor markets. Others, starting from Marx's distinction between work ("labor") and labor time ("labor power") have developed an analysis of class conflict within the firm.

A careful reading of this diverse body of literature suggests that there are many common points of reference. All, for example, have stressed the social and nonmarket aspects of the production process.<sup>1</sup> But there are important differences as well.

In this essay I develop an underlying microeconomic logic of the Marxian model, and contrast it with two alternative views. The first is the simple Walrasian model in which the production process is represented as a set of input-output relations selected from an array of feasible technologies by a

process of cost minimization with respect to market-determined prices. The Walrasian model presents no analysis of the internal social organization of the firm.

The second group of models stems from Coase's seminar work, and is exemplified by the important recent contributions of Armen Alchian and Harold Demsetz (1972), Oliver Williamson (1980), Guillermo Calvo (1979), Edward Lazear (1981), and others. Like the Marxian approach, and unlike the Walrasian, these models present a well-developed model of the firm as a social organization. I refer to these models as neo-Hobbesian because according to them the key to understanding the internal structure of the firm is the concept of malfeasance. Also known as shirking or free riding, malfeasance gives rise to the archetypal Hobbesian problem of reconciling self-interested behavior on the part of individuals with collective or group interests. Moreover, the neo-Hobbesian explanation of the functional nature of the hierarchical organization of the modern workplace bears a close resemblance to the original Hobbesian rationale for the state as a socially necessary form of coercion.<sup>2</sup>

By contrast, the basic commitment of the Marxian models is to the fundamental importance of class as an economic concept. While the Marxian model does not deny the importance of the Hobbesian conflict between individual and collective rationality as an underlying social problem central to an understanding of the production process in any social system, it focuses on those problems which may be traced to the structure of

\*Department of Economics, University of Massachusetts, Amherst, MA 01003. I have benefited greatly from the comments and criticisms of my colleagues at the University of Massachusetts and the University of Siena, particularly Robert Costrell, Kenneth Flamm, Herbert Gintis, Richard Goodwin, Donald Katzner, Michael Kruger, Fabio Petri, Ugo Pagano, and Leonard Rapping. I also thank David Gordon, Robert Boyer, Frank Hahn, James Malcolmson, Robert Solow, Juliet Schor, Robert Gordon, Duncan Foley, and two anonymous referees for criticism and comments, and the John Simon Guggenheim Foundation and the German Marshall Fund of the United States for financial support.

<sup>1</sup>The list of approaches is quite partial as it excludes, for example, the interesting and related work on social norms and economic processes. See George Akerlof (1980) and Robert Solow (1980).

<sup>2</sup>Thus, for example, it is argued that a team of workers would rationally hire a supervisor to monitor their work activities, an economic analogue to the Hobbesian position which asserts that uncoerced citizens in a state of nature would in their own interests commit themselves to obey the dictates of a state.

ownership and control of the means of production.<sup>3</sup>

What is at issue between Marxian and non-Marxian economists is not the general relevance of class concepts to the analysis of social groupings, institutions, or political action, but the status of class as an *economic* concept. Even within the realm of economics, terminological differences aside, there is general agreement on the relevance to a wide range of issues of what Marxian economists would term the class structure. Few economists of any persuasion would question the importance of the distribution of the ownership of assets as a determinant of the distribution of income, patterns of consumption, or levels of saving.

The Marxian model is distinct, however, in that it asserts that consideration of the ownership of the means of production, and the command over the production process which this ownership permits, is essential to a coherent analysis of the production process itself, and to the analysis of market equilibration and competition. It is thus not only in its macroeconomic theory and its theory of collective action that the Marxian model makes substantive use of the idea of class, but in its microeconomics as well.<sup>4</sup>

The distinctiveness of the Marxian microeconomics with respect to the neo-Hobbesian and Walrasian approaches, as we shall see, has little to do with the labor theory of value, however. Its primary focus is on the interactions between the voluntary relations of the marketplace and the command relationships of the workplace. Thus Marxian economists take strenuous exception to Paul Samuelson's assertion that "in the competitive model it makes no difference whether capital hires labor or the other way around" (1957, p. 894).

The structure of the Marxian model may be illustrated by reference to three propositions central to its analysis of capitalist production.

First, capitalists (owners of firms or their representatives) will generally select methods of production which forego improvements in productive efficiency in favor of maintaining their power over workers. For this reason, the technologies in use in a capitalist economy, as well as the direction of technical change, cannot be said to be an efficient solution to the problem of scarcity, but rather, at least in part, an expression of class interest. This proposition is fundamental to the Marxian assertion that the productive potential of a society (the "forces of production") is inhibited (or "fettered") by the specifically capitalist institutional structure of the economy (the "social relations of production").

Second, it will generally be in the interest of capitalists to structure pay scales and the organization of the production process to foster divisions among workers, even to the extent of treating differently workers who are identical from the standpoint of their productive capacities. This proposition is central to the Marxian divide and rule interpretation of internal labor markets, segmented labor markets, and discrimination.

Third, involuntary unemployment is a permanent feature of capitalism central to the perpetuation of its institutional structure and growth process. In a capitalist economy, product and labor markets will not function so as to eradicate Marx's familiar "reserve army of the unemployed." Moreover, even public policy towards this objective will be unable to maintain full employment.

To economists trained in the Walrasian or more generally neoclassical tradition, these assertions are often thought to be either nonsensical, or based on a radically different model of production and competition. Specifically, it is often thought that these propositions require one or more of the following assumptions: that capitalists collude in pursuit of their collective interests, that capitalists do not maximize profits, that product and factor markets are not competitive, or that the economy is characterized by im-

<sup>3</sup>I will specify what I take to be the principal differences between the neo-Hobbesian and the Marxian models in the penultimate section. The relationship between the Marxian model and what Marx wrote is suggested in various notes.

<sup>4</sup>I would thus take strong exception to Oskar Lange's (1935) view that the specificity and strength of Marxian economics resides in its institutional and sociological content and not in its microeconomic theory per se.

portant institutional rigidities such as sticky wages. Under these assumptions, it is not difficult to demonstrate the above propositions and thus affirm the importance of the Marxian concept of class.

But, while sufficient, these assumptions are not necessary to the demonstration of the above basic propositions of Marxian economics. (Nor, one might add in passing, are they particularly central to Marx's own theoretical writings, which generally presumed a highly competitive economy based on profit maximization.) The basic difference between the Marxian and Walrasian models is thus not in the structure of markets or in concepts of collective vs. atomistic action, or in institutional rigidities, but in the analysis of the process of production itself, or in what Marxists term the labor process.<sup>5</sup>

In this essay I develop a simple model of the production process in a competitive capitalist economy. To the familiar two-equation Walrasian model of production (production function and cost function), I add a third equation representing class conflict within the production process. I then derive the above three propositions from the expanded model. I close with some observations on the closely related but quite distinct neo-Hobbesian model of the production process.

My intent is not so much to advance the discussion of technical change, discrimination, or involuntary unemployment per se, as to provide a single coherent microeconomic framework capable of integrating important modern Marxian contributions in these fields. To cite only a few: those of Stephen Marglin (1974), William Lazonick (1982), and Harry Braverman (1974), on technology; of Richard Edwards, David Gordon, and Michael Reich (1982), Herbert Gintis (1976), and John Roemer (1979), on divide and rule strategies; and of Michel

Kalecki (1943), Andrew Glyn and Robert Sutcliffe (1972), Raford Boddy and James Crotty (1975), and Richard Goodwin (1967), on unemployment.

### I. The Extraction of Labor from Labor Power

The Marxian model comprises an analysis of three quite distinct aspects of the production process, broadly construed: market exchanges (modeled as voluntary contractual or contract-like interactions), physical input-output relations (which in principal might be represented by an engineering production function), and social relationships among workers and between workers and their employer (which are modeled in an entirely different manner).

Central to the Marxian approach is the distinction between those social relationships that take the form of market exchanges between firms and other ownership units, on the one hand, and relationships of command that take place within firms. The market arena in which contractual exchanges take place, Marx termed "a very Eden of the innate rights of man." By contrast the internal structure of the firm—which Marx termed the "hidden abode of production"—is represented (as Coase was later to do) as a mini-command economy.<sup>6</sup>

The distinction between the two types of social relationships would be of little theoretical importance, of course, if the command relations of the firm were simply effects entirely derived from the technological struc-

<sup>6</sup> The distinction is perhaps the most fundamental in Marxian economics. Marx wrote:

If we consider the exchange between capital and labor, then, we find that it splits into two processes which are not only formally but also qualitatively different...: (1) the worker sells his commodity... (labor power)... which has... as a commodity... a price.... (2) The capitalist obtains labor itself... he obtains the productive force which maintains and multiplies capital.... The separation of these two processes is so obvious that they can take place at different times and need by no means coincide. The first can be and usually, to a certain extent, is completed before the second even begins.... *In the exchange between capital and labor the first act is an exchange and falls entirely within ordinary circulation; the second is a process qualitatively different from exchange, and only by misuse could it have been called any kind of exchange at all.* [1973, pp. 274–75]

<sup>5</sup> Partly as a result of the differing treatment of the labor process and partly for other reasons, the Marxian and Walrasian views of the competitive process differ somewhat. Both stress the importance of unlimited entry and a multiplicity of buyers and sellers. Marxists, however, generally assume price-making rather than price-taking behavior by firms.

ture of production and the market relationships into which the firm enters. Indeed, this is precisely the logic of Samuelson's remark quoted above.

But, according to the Marxian model, the structure and effects of the social relations within the firm—of command, cooperation, competition, and the like—while influenced by technology and market relations, are not entirely reducible to them, but rather depend on the class structure of the productive process, and hence require a distinct form of modeling. By contrast, Walrasian theory denies the need for a distinct modeling of the social relationships within the firm, while the neo-Hobbesian approach insists that a distinct modeling of the firm as a command economy is necessary, but has nothing to do with the class structure, for hierarchical relationships between managers and workers reflect nothing more than an efficient solution to the universal problem of malfeasance.

The importance of the social structure of the firm, the necessity of a distinct modeling of these social interactions, and the centrality of the class structure to their analysis may be traced within the Marxian model to three characteristics of the production process. First, labor is embodied in people, and hence labor services are inseparable from the person supplying the service. Second, whether for reasons of technology or of economies of supervision, production is generally less costly when it is done by a considerable number of workers together in one location. And third, the production process is always a process of joint production, as the workers' attitudes, capacities, and beliefs are transformed in the production process as surely as the raw materials and other goods in process are transformed into final outputs. I will refer to these three characteristics respectively as the human embodiment of labor, the social nature of production, and the endogeneity (or joint production) of workers.

Two types of social interaction within the firm are central to understanding the production process: relations among workers (of competition, solidarity, or whatever) and relations between workers and their employer. I focus on the second at the outset, representing the capital-labor relationship as a

simple bilateral relationship between two individuals. Relations among workers will be introduced later.

The relationship between workers and their capitalist employer is formally structured by the ownership and control of the means of production. It is thus (by definition) a class relationship. In what follows, two characteristics of this relationship will be central. Both may be considered axioms with respect to the proposition to be demonstrated below. First, quite apart from the level of wages, employers and workers have a conflict of interest in the production process in the specific sense that the employer's interests (as measured by profits) are enhanced by being able to compel the worker to act in a manner that he or she otherwise would not choose. This conception of a conflict of interest does not imply that the employer and the worker have no common interests, or that, if left to their own devices, labor would choose not to produce anything at all. It simply states that within a given legal and economic context, the employer can do better than to simply hire workers and let them work as they please. The level of profits therefore depends—at least to some extent—on the power of capital over labor.

While this conflict of interest may extend to such issues as the safety or comfort of the workplace and the amount, type, and location of new investment, I focus in what follows on the conflict over the amount of work done per hour, or what may be termed the intensity of labor. This is often termed the conflict over extraction of labor from labor power. It might better be called the extraction of work from the worker.

The second axiomatic characteristic of the capital-labor relationship is that the strategies that capital may adopt in order to enhance or exercise its power over labor are costly. The basis of the power of capital over labor is the ability of the owner to impose costs on workers who refuse to (or otherwise fail to) carry out the wishes of the employer. In liberal capitalist societies, the only means by which this cost may be imposed is via the employer's control over the terms of employment (wage and other conditions) and the possibility of job termination. For reasons of

simplicity, I focus initially on the threat of job loss.

The expected cost to the worker of resisting (or otherwise not carrying out) the command (explicit or implicit) of the employer will depend on the likelihood that the worker's resistance will be detected, and on the cost to the worker of losing his or her job. (Assume for the present that any worker who is observed performing below the employer's expectation will be fired; I will later modify this assumption.) Because the cost (to the worker) of job loss will depend on the wage, enhancing the threat of job loss (by raising the wage) will be costly to the employer. Similarly, the employer cannot costlessly know what each worker is doing at any given moment even if the employer knows all of the workers' production capacities and personality characteristics. However, the employer can increase the probability of detecting below-standard work intensity through employing surveillance personnel and equipment, and by using production methods that produce (as a joint product) information on individual worker performance. Both methods of enhancing the worker's expected cost of working below expectation are thus costly to the employer.

These two characteristics of the production process—the conflict of interest between capital and labor, and the costliness of employer strategies—form the basis of the propositions that follow. The underlying reasoning may be made more precise with the aid of a simple model.

Let us assume that labor is homogeneous, that the employed and unemployed are otherwise indistinguishable, that there are no employer costs of selection or on-the-job training, that workers are risk neutral, and that all markets are competitive in the sense of a multiplicity of noncolluding buyers and sellers.<sup>7</sup>

<sup>7</sup>Unlike search models or Arthur Okun's (1981) toll model, I assume that workers have complete information about job and wage conditions throughout the economy, that employees know all (actual and potential) employee characteristics, and that what Okun called "the attachment between employer and employees (mutual),...the key component of the toll model that was absent in the simple search model" (p. 75) is absent

Let the output of a firm be a function of the level of inputs.

$$(1) \quad Q = f(X, L),$$

where  $Q$  is the number of units of output over some period of time,  $X$  is the vector of material inputs and services, and  $L$  is the input of labor over this same time period. All inputs and output are measured in physical terms. Labor is thus counted in effective work done, or effort units. For simplicity, the price of the output is taken by the firm as given and is set equal to one.

As is quite evident, the treatment of total sales and the physical input-output aspect of production in the model is similar to its neoclassical—or Walrasian—analogue. The difference emerges when we consider the cost function. The labor argument in the production function—work effort—bears no market price, for it is labor time, not work itself, that is purchased. Hence the cost of labor—work—cannot be expressed in the firm's cost function as a market-determined hourly wage rate multiplied by the number of labor hours hired.<sup>8</sup> To express the cost function and the

---

here as well. Unlike contract theory, I assume away problem of risk aversion and issues of reputation (workers and capitalists alike have no memories).

<sup>8</sup>Marx (1976) dramatized the fact that labor itself cannot be bought and hence has no price as follows. "On the surface of bourgeois society the worker's wage appears as the price of labor, as a certain quantity of money that is paid for a certain quantity of labor" (p. 675). But "it is not labor which daily confronts the possessor of money (the capitalist, SB) on the commodity market, but rather the worker. What the worker is selling is his labor power" (p. 677). As a result, "according to the amount of actual labor supplied every day, the same... wage may represent very different prices of labor, i.e., very different sums of money paid for the same quantity of labor" (p. 683). Marx then makes it clear that the cost of a given amount of labor may vary through the extension of the length of the working day, or through an increase in the intensity of work in any given hour. "The rise in... wages may therefore be unaccompanied by any change in the price of labor, or may even be accompanied by a fall in the latter" (p. 684). Henry Ford may have understood this when he paid his workers in Detroit the unheard of sum of \$5 a day. That labor itself cannot be purchased has long been recognized outside the Marxian tradition as well. Gary Becker observed that "any enforceable contract could at best specify the hours required on a job, not the quality of the performance" (1962, p. 6). But this fact has not been given the importance it has received among Marxian economists.

production and total sales function in the same terms, a third equation is required—the labor extraction function—representing the amount of labor done per hour of labor hired as a function of the costly inputs used to elicit work from workers.<sup>9</sup>

We may write  $L$ , the total labor input, as the product of the hours of labor power hired,  $Lp$ , and the amount of work done per hour  $l^*$ , or  $L = Lpl^*$ . The amount of work done per hour is determined by the worker in response to the constraints devised by the employer, given the availability of other jobs, unemployment insurance, and the like. At this point, attention need only be given to those determinants of the worker's effort that appear as instruments from the standpoint of the employer.

The amount of work done per hour will depend upon the worker's perception of the cost of pursuing a nonwork activity, that is, of acting on the basis of any of his or her nonwork (and work-reducing) objectives. Assuming that a worker's job will be terminated if the worker's nonwork activities are detected, the expected cost of pursuing nonwork activities,  $E(n)$ , is the product of two terms: the probability that a worker's nonwork strategy will be observed by the employer,  $p^o$ , and the cost of being fired, if observed,  $w^*$ . It is assumed that  $p^o$  is positively affected by the amount of surveillance inputs (material or human) purchased per

hour of production labor hired,  $s$ , or  $p^o = p^o(s)$ , and  $p^o(0) = 0$ , and  $p_{os} > 0$  for  $s > 0$ . (Here and below subscripted functions indicate the partial derivative of the function with respect to the variable indicated by the subscript.)

Surveillance labor does not enter into the transformation of inputs into outputs, and is thus distinct from what may be termed coordination labor, which is a production input represented in the production function as a component of  $L$ . (Here I abstract from the far from trivial problem of extracting work from surveillance employees. Thus I represent surveillance services,  $s$ , as purchasable at price  $p_s$ .) The cost of an hour of labor power,  $c_{Lp}$ , is thus  $(w + p_s s)$ , and the cost of an effort unit of labor,  $c_l$ , or what Marx called the price of labor, is  $(w + p_s s)/l^*$ .

The money cost of being fired is measured by  $w^*$ , the difference between the wage offered and the worker's expected income if fired. (I assume for simplicity that the worker has no nonwage income if employed.) This latter term is simply a weighted average of  $w^c$ , the worker's nonwage income if fired and not reemployed (unemployment insurance, means-tested income support payments, and the like), and  $\hat{w}$  the expected wage in some other job, should the fired worker find employment elsewhere. It is assumed that both wages ( $w, \hat{w}$ ) exceed  $w^c$ . Thus assuming a time horizon of a single period and letting  $j$  represent the probability of finding another job (or equivalently, the fraction of the period during which the worker expects to remain unemployed), the expected income loss,  $\hat{w}^d$ , is

$$\hat{w}^d = w - [j\hat{w} + (1-j)w^c].$$

All of these wage terms, including  $w^c$ , are expressed in real units.<sup>10</sup>

A particularly simple model of the worker's response to the employer's choice of various

<sup>9</sup>Note that if labor costs did *not* depend on hours of labor hired but only on the amount of labor done, or if the relationship between hours hired and work effort performed were exogenously determined, or if the extraction of work from workers were costless, the third equation would be unnecessary. However, even the use of straight piece-rate payments will not render costs independent of the hours of labor hired unless the piece-rate workers use no inputs owned by the firm, and the determination of the number of pieces produced requires no surveillance inputs and hence is costless. But in this extreme case, there is no reason—by conventional definitions—to consider the piece-rate workers part of the firm that purchases their output, for their sole relationship to the firm is an exchange. The necessity for the third equation is thus based on assumptions no different from those used in the Coasian tradition to explain the existence of firms. The manner in which this function is developed is quite different, as we shall see, from its Coasian analogue.

<sup>10</sup>Note that because the employer clearly may directly set only nominal variables, but seeks to implement a real strategy, the general price level will enter into the employer's wage setting even in the absence of cost-of-living provisions in contracts. But I will not develop this point here.

P 3125 (3125)

combinations of surveillance and wage-loss threat results if we assume that at any moment the worker's decision is to work at a level of intensity satisfactory to the employer or not to work. The intensity of labor,  $l^*$ , then is just the percentage of time on the job during which the worker is actually working. It is assumed that the worker chooses a desired level of  $l^*$ , and then selects the moments of work and nonwork randomly. The probability that the worker will be detected not working, and hence dismissed, ( $p^d$ ), is equal to the probability of being observed at any moment ( $p^o$ ), multiplied by the probability that at that moment the worker will not be working ( $1-l^*$ ), or  $p^d = p^o(1-l^*)$ . The probability of job retention is simply  $(1-p^d)$ , setting aside reasons for job termination other than observed nonwork. Thus, for  $l^*=1$ ,  $p^d=0$ .

Let us assume for simplicity a two-period framework in which hiring occurs only at the beginning of a period and firing occurs only at the end of a period. The worker's time preference is assumed to be zero. The worker's expected income over two periods is thus the first-period's (assured) wage plus the expected wage or nonwage income for the second period:

$$\hat{y} = w + (1-p^d)w + p^d(j\hat{w} + (1-j)w^c).$$

Assuming identical workers and employers makes it reasonable to represent the worker as perceiving the alternative wage as identical to the present wage, or  $w = \hat{w}$ , and thus the expected income in the second period, if dismissed at the end of the first period would be  $w - \hat{w}^d$ , and rewriting the above expression for  $\hat{y}$ :

$$(2) \quad \hat{y} = 2w - p^d\hat{w}^d.$$

The worker's expected effort over two periods is both the effort expended in the current job, and the effort expended in the next job, should the worker be terminated and then reemployed. (Given the assumption that the worker has full information and hence nothing to learn, it is reasonable to suppose that the worker's choice concerning work effort when reemployed will be identical to the

prejob loss choice.) Thus, the expected level of effort is

$$(3) \quad \hat{l}^* = l^* + (1-p^d)l^* + p^djl^*.$$

The worker values income and, on the margin at least, finds increased work intensity displeasing.<sup>11</sup> The risk-neutral worker's response to the employer's strategy will be that which maximizes

$$(4) \quad \hat{u} = \hat{u}(\hat{y}, \hat{l}^*)$$

by equating the expected marginal disutility of effort (from equations (3) and (4)) with the expected marginal utility of income associated with an increment of effort (from equations (2) and (4)).<sup>12</sup>

Because the expected marginal income return to an increment in work will depend positively on  $\hat{w}^d$ , under quite general assumptions it can be shown that the worker's choice of  $l^*$  will be a positive function of  $\hat{w}^d$ .<sup>13</sup> By similar reasoning it can be shown that work intensity will be a positive function of  $s$ .

We may now represent the amount of work done per hour of labor power pur-

<sup>11</sup>This does not require a marginal disutility of labor (or effort). Even on the margin, the worker may enjoy the process of work, or despise it; what is essential to my argument is the assumption that the workers' objective function includes some positively valued on-the-job activities (or inactivity) that are associated with a positive opportunity cost in terms of working.

<sup>12</sup>That is, by equating  $(\partial u / \partial \hat{y})(\partial \hat{y} / \partial l^*)$  with  $-(\partial \hat{u} / \partial l^*)(\partial \hat{l}^* / \partial l^*)$ .

<sup>13</sup>Assuming the second-order conditions for the worker's utility maximization to be met, it can be shown that effort will be an increasing function of  $\hat{w}^d$  for  $\hat{w}^d \geq 0$ ,  $l^* < 1$ , and  $s > 0$ . This is because an increase in  $\hat{w}^d$  will increase  $(\partial \hat{u} / \partial \hat{y})(\partial \hat{y} / \partial l^*)$ . This follows readily from the independence of  $\partial \hat{u} / \partial \hat{y}$  from  $\hat{w}^d$ , and the fact that  $\partial \hat{y} / \partial l^* = p^d\hat{w}^d$ . Thus,  $(\partial^2 \hat{y} / \partial l^* \partial \hat{w}^d)$  must also be positive (for  $s, \hat{w}^d > 0$ ). The upward shift of  $(\partial \hat{u} / \partial \hat{y})(\partial \hat{y} / \partial l^*)$  associated with an increment in effort will necessarily result in an increase in effort as long as the disutility associated with a marginal increment in effort is not infinite. Thus the derivative of work effort with respect to the cost of job loss will be positive for positive  $\hat{w}^d$  and  $s$ . Assuming the expected marginal utility of effort is independent of  $s$ , the analogous result for  $s$  follows.

chased,  $l^*$ , as

$$(5) \quad l^* = h(s, \hat{w}^d).$$

The function  $h$ —the labor extraction function—summarizes the effects of all of the relevant preferences of the worker, as well as the worker's sense of commitment, injustice, resentment, deference, patriotism, or whatever may affect the difficulty or ease of extracting labor from labor power, or influence the efficacy of surveillance or the threat of income loss as instruments towards this objective.<sup>14</sup>

<sup>14</sup> Before bringing together the three functions—production, cost, and extraction—to consider formally the capitalist's profit-maximizing problem, it may be useful to scrutinize more carefully the nature of the extraction problem. Is this not just another case of the economics of lemons, in which the employer must pay some costs to find out which workers will work hard (or well) and which will not? While some of the results are similar, not all are, and the mechanisms are quite different. The problem for the employer is not to find out what the worker *is*, but to find out what the worker *does*. To see that this is the case, the extreme assumption is made that the employer may know at zero cost the workers' skills and personality characteristics relevant to work motivation and capacities, including exact knowledge of the determinants of the typical (and therefore every) worker's work effort. One of the determinants of work effort is the threat of job loss and hence the level of surveillance. The employer, by these assumptions, knows exactly how much work each worker will do on the average once the employer has selected the level of surveillance and the wage (given external wages, unemployment probabilities and unemployment insurance). At a given moment, however, the employer does not know what the worker is doing, unless the worker is being observed at that moment. And unless the worker is observed not working up to standard, it would not be rational for the employer to fire him or her, for this would convince the remaining workers that the probability of job loss did not depend on work effort, and would thus lower the efficacy of the surveillance inputs. Note that by firing the worker the employer does not eliminate a "bad worker" in favor of a chance at getting a "better worker" from the unemployment pool, for all workers are identical. The purpose of firing the nonworking worker is to convince workers that the surveillance system is effective, and that firing is related to low work effort. In other words, without firings or with firings not based on observed low work effort, the  $h$  function would shift adversely from the standpoint of the employer. Strictly speaking, then, the cost of surveillance is not an information cost at all (or at least a very peculiar one) as surveillance will affect increases in effort (over

It is assumed that the employer knows the  $h$  function of each worker, and that each is identical, thus allowing one to argue in terms of a representative worker. Further, on the basis of the reasoning above, for both  $s$  and  $\hat{w}^d$  positive and  $l^* < 1$ ,  $h_s$ , and  $h_{\hat{w}^d}$  are positive, and  $h_{s\hat{w}^d}$  is also positive.<sup>15</sup>

Letting  $p_x$  represent a vector of prices of nonlabor inputs, the problem for the employer is now to maximize

$$(6) \quad R = f(X, L) - p_x X - (w + p_s s) L p,$$

subject to

$$(7) \quad L = l^* L p = h(s, \hat{w}^d) L p,$$

or to maximize

$$(8) \quad R = f[X, h(s, \hat{w}^d) L p] \\ - p_x X - (w + p_s s) L p.$$

Because it has been assumed for the moment that the nonlabor inputs  $X$  do not affect the labor extraction process, the production function and the extraction function

some range) even if the "surveillors" do not pass the information along to the employer, as long as the workers believe that the probability that a nonwork strategy will be detected is a positive function of the level of surveillance. But if employers know exactly how much work each worker will do once the wage and level of surveillance is selected, would it not be optimal to pay workers according to the amount of work done? It might. But this in no way would affect the results below, for the firm's costs will still depend on the number of hours hired (because surveillance  $s$  is proportional to hours of labor engaged, not the amount of work done and because workers use inputs owned by the firm). And as long as costs are not independent of the number of hours hired, employers will not be indifferent to how hard each particular worker works. (We will see below that the limiting case of no surveillance inputs cannot be optimal. It is, of course, possible to devise combinations of incentive pay and surveillance such that costs would be independent of hours hired. But it would be quite accidental if that scheme coincided with the optimal incentive structure, given workers' preferences and other relevant information.)

<sup>15</sup> More formally, because the derivative of expected income with respect to work intensity is simply  $\hat{w}^d p^d$ , the effect of an increase in  $\hat{w}^d$  on the workers optimal effort level will depend positively on the level of  $s$ , and conversely.

(equations (1) and (5)) are separable, and the employer's maximizing problem may be solved sequentially. The first problem for the employer, and the one that interests us here, is to minimize the cost of a unit of work done, or

$$(9) \quad \min c_l = (w + p_s s) / h(s, \hat{w}^d).$$

Having solved this problem, its solution,  $c_l^0$ , can then be considered the minimum cost of a unit of labor and entered into the employer's new maximand

$$(8') \quad R = f(X, L) - c_l^0 L - p_x X.$$

Assuming, for the moment, an interior solution, and noticing that the marginal cost of a unit increase in  $\hat{w}^d$  is one by definition, minimizing (9) requires that

$$(10) \quad h_{\hat{w}^d} = h(s, \hat{w}^d) / (w + p_s s) = h_s / p_s,$$

or that the average effort per dollar of wage and surveillance cost equal the marginal effort per dollar increase in either wage cost or surveillance cost. Analogously the profit-maximizing employer's strategy must satisfy the condition

$$(10') \quad p_s = h_s / h_{\hat{w}^d},$$

or the price of surveillance must be equal to the "marginal rate of substitution" between income loss if fired and probability of detection in the labor-extraction function (5).

We may represent this graphically as in Figure 1. The isocost function is a locus of equally costly employer strategies. Because the cost to the employer of a unit increment in  $\hat{w}^d$  is one by definition, the slope of the isocost function can be seen to be  $-p_s$ . The isowork function, derived from the labor extraction function (5), is one of a family of loci of equally effective employer strategies: points describing an equal extraction of labor from a given number of hours of labor power hired. Its slope is  $-h_s / h_{\hat{w}^d}$ . The expansion path is the locus of all possibly profit-maximizing strategies, namely, those satisfying (10'). Some point on the expansion path, say point  $a$ , minimizes the cost of a unit of labor

FIGURE 1

and is therefore the solution to (9) and is the profit-maximizing strategy. (It cannot be read directly off the figure.)

I now use this model to demonstrate the three substantive propositions with which I began.

## II. The Reserve Army of the Unemployed

The more or less permanent existence of involuntary unemployment is central not only to the Marxian critique of capitalist society, but to the analytical underpinnings of its theory of profit (or of surplus value) as well. Because profits in the Marxian model are not a return to a scarce input but are simply a deduction from total output made possible by capital's power over labor, a complete Marxian model must provide a compelling account of how this power is perpetuated in an economically competitive and politically liberal environment. The basis of this account is the asymmetry between two forms of competition: that among capitalists in selling their outputs and that among workers in seeking employment. Because profit is not the return to a scarce input, in the absence of such an asymmetry, there would be no reason why price competition among capitalists would not drive the profit rate to zero.

The necessary asymmetry is based on the permanent existence of involuntary unemployment, or what Marx termed the reserve

army of the unemployed.<sup>16</sup> The effect of involuntary unemployment is to render labor power nonscarce and hence incapable of claiming the whole product (net of depreciation) through the normal process of competitive price and wage determination. The puzzle is then no longer why profits are not competed away, but why does a nonscarce input, labor power, receive any competitive remuneration at all. The capital-labor distributional conflict thus appears as one taking place between and among two sets of actors, none of which exercise their claims on the product on the basis of a competitively determined return to scarcity in the usual general equilibrium sense.

The Marxian solution to this puzzle is to not reject the competitive assumptions underlying the general equilibrium model, but to pose a distinct theory of the long-term determination of wages and effort in which the former varies negatively and the latter positively with the level of unemployment.<sup>17</sup> Only *involuntary* unemployment will affect the bargaining power of capital and labor; hence the centrality of involuntary unemployment to the Marxian theory of the capitalist economy.

On what basis can involuntary unemployment be represented as a general—rather than ephemeral—characteristic of the capitalist economy? The endogenous perpetuation of the reserve army of the unemployed could be assured by a variety of mechanisms: for example, an infinitely elastic supply of labor from other countries or from declining domestic noncapitalist economic systems, such as household production, or rapid structural and technical change accom-

panied by downwardly sticky wages.<sup>18</sup> The above model of the extraction of labor from labor power points to another possibility, and one more consistent with competitive assumptions, namely, that the labor market does not clear in equilibrium. Put somewhat differently, excess supply in labor markets does not imply a competitive response of wage reductions.

By equilibrium in the labor market, I mean a level of wages, employment, and labor intensity that none of the agents would have both the motivation and the ability to alter. A non-clearing-labor-market equilibrium requires that profit-maximizing employers offer workers a wage and surveillance package such that, given the levels of work effort that workers will choose to expend under the package offered, workers are not indifferent between working and being unemployed. This is, of course, tantamount to saying that a profit-maximizing employer would refuse the offer by a currently unemployed worker to work as hard as the current work force for a wage less than the current wage. We shall see why this counterintuitive result may quite generally occur.

It is clear then that a market-clearing wage would imply that in our model the cost of job loss is zero, for if the cost is not zero the worker cannot be indifferent between employment and unemployment. Under what conditions could a wage-surveillance package that rendered the worker indifferent between employment and nonemployment be a profit-maximizing strategy for the individual employer, and hence a possible equilibrium? Or, in terms of Figure 1, could an optimal strategy lie on our horizontal axis, indicating a zero income loss associated with being fired? Because  $h_s \rightarrow 0$  as  $\hat{w}^d \rightarrow 0$ , and analogously  $h_{\hat{w}^d} \rightarrow 0$  as  $s \rightarrow 0$ , the expansion path for any  $p_s > 0$  will lie entirely within the range of positive values of  $s$  and  $\hat{w}^d$ . As long as the employer has hired some surveillance inputs, a market-clearing wage ( $\hat{w}^d = 0$ ) can-

<sup>16</sup> Marx (1976): "...relative surplus population (i.e., unemployment, SB) is therefore the background against which the demand and supply of labor does its work" (p. 792). And, "The pressure of unemployment compels those who are employed to furnish more labor and therefore makes the supply of labor to a certain extent independent of the supply of workers. The movement of the law of supply and demand on this basis completes the domination of capital" (p. 793).

<sup>17</sup> The macroeconomic and general equilibrium characteristics of this solution are the subject of two of my other papers (1983a,b).

<sup>18</sup> If the supply of labor hours is infinitely elastic at a given wage, those who are not employed cannot be said to be involuntarily unemployed strictly speaking, as they are unwilling to offer any labor time at a lower wage.

not be optimal (because  $h_s = 0$  for  $\hat{w}^d = 0$ ). The critical role of the cost of surveillance is here clearly indicated, for with  $p_s = 0$  the isocost functions in Figure 1 would be horizontal: (free) surveillance would be substituted for (costly) job loss threat and the cost minimum would occur at  $\hat{w}^d = 0$ , a result consistent with the traditional market-clearing equilibrium.

But what of the "no income loss, no surveillance strategy" represented by the origin in Figure 1? In order for this strategy to be optimal, it would have to be the case that

$$(11) \quad h(0,0)/w > h(s, \hat{w}^d)/(w + p_s s)$$

for all possible levels of  $s$  and  $w$ . In this case, surveillance and job loss threats are sufficiently ineffective or costly to prohibit their use at any level. But this implies that, even when it is possible for the employer to exercise power over the worker, it is not profitable to do so. But this could only be true if there were no conflict of interest between the worker and the employer. In this case, employer and workers have a "conflict of interest" only in the socially irrelevant sense that sunbathers and drought-stricken farmers have a conflict of interest (barring the possibility of rainmaking).

This result does not depend on the manner in which the probability of reemployment ( $j$ ) is determined. Assume for the moment that the government committed itself to achieving full employment, either through fiscal and monetary policy, or simply by guaranteeing any unemployed worker a job at the going wage. With  $j=1$  the employer might either set  $\hat{w}^d > 0$  by offering a wage higher than other employers, or set  $\hat{w}^d = 0$ . The former is inconsistent with equilibrium. This can be readily seen by rewriting the cost of being fired as an equilibrium condition (with  $w = \hat{w}$ ) or  $\hat{w}^d = (1-j)(w - w^c)$ . By the logic of the previous paragraph, the latter is inconsistent with the assumed conflict of interest between worker and capitalist.

Let us summarize these results. Given a positive cost of surveillance and a conflict of interest between employer and worker over work effort, the wage rate offered by the

competitive profit-maximizing employer will exceed the worker's next best alternative. This is possible in general only if the probability of reemployment is less than one. Therefore, labor market competition cannot clear the labor market. Correspondingly, market clearing—the absence of involuntary unemployment—implies labor market disequilibrium.<sup>19</sup>

Other than ruling out market clearing as a possible labor market equilibrium, this model bears no direct implications concerning the determination of the general level of unemployment or the probability of reemployment. But it does provide a microeconomic foundation consistent with Kalecki's suggestion that sustained full employment and the long-run survival of capitalist enterprise may be inconsistent. Indeed, given a conflict of interest between employer and worker, labor market clearing implies either escalating wage increases, or a reduction in work effort to those levels chosen by workers. Particularly in an open economy, neither result would likely be conducive to investment levels capable of sustaining full employment (but to pursue this argument we would have to go considerably beyond the microeconomic confines of this paper).<sup>20</sup>

These results would be modified, of course, if employers were assumed to have not pro-

<sup>19</sup>This result is similar to that produced—with somewhat different models—by Calvo, B. Curtis Eaton and William White (1982), James Malcomson (1981), Hajime Miyazaki (1981), Tekashi Negishi (1979), Solow (1980), Carl Shapiro and Joseph Stiglitz (1984) and others. In all of the above, actual amount of work done is directly or indirectly a positive function of the wage rate. Miyazaki focuses on the problem of worker free riding against other workers in a work group. Eaton and White focus on "trust jobs." Malcomson assumes "at least two types of individuals with different productivities who cannot be discriminated perfectly by observation at work" (p. 865). Negishi and Solow both base their models on problems of worker morale and "affront" (Negishi, p. 114). Closest in spirit to my model (though lacking the surveillance element) is Calvo, who, however, while demonstrating the possibility of nonclearing equilibria, assumes an interior solution to a problem analogous to the minimization of (6), thus eliminating the market-clearing equilibrium by assumption.

<sup>20</sup>I develop this argument in my 1981, 1983a, b papers. See also Gintis and Tsuneo Ishikawa (1983).

hibitively expensive ways of imposing effective sanctions on workers even in the absence of involuntary unemployment. The extent to which such alternative sanctions are feasible and effective is in part an empirical issue that cannot be resolved here. For whatever reason, the practical import of most of the alternatives to the threat of involuntary unemployment appears to be quite limited in the U.S. economy.<sup>21</sup>

### III. Capitalist Technology

Central to the Marxian critique of capitalist society is the idea that the competitive pursuit of profits requires employers to organize the production process so as to maintain their power over workers, and that at least some of the boredom, fragmentation, and other undesirable aspects of the work experience may be attributed to this fact and not to the requirements of technical rationality. According to this view, the prevailing organization of production—including the technologies in use—cannot be derived solely from an interaction of exogenously given technical possibilities and worker and consumer preferences for goods, leisure, and various kinds of work environment, but rather reflect the class interest of capital as well. Hence the expression “capitalist technology.”

To suggest that technology may be an instrument of class conflict does not mean, of course, that employers may select technologies without regard to the competitive requirements of cost minimization. Nor does it require that capitalists collude in their choice of production methods or in the development of future technologies. Rather, the concept of capitalist technology is based on the proposition that cost minimization by competitive employers implies the selection of profitable but inefficient technologies even in the absence of market failures arising from collusion, externalities, extended time horizons, and the like.

I will say that the capitalist has chosen an inefficient technology when there exists some other method of production that, per unit of output, uses less of at least some input and not more of any. The logic of the concept of capitalist technology is that a technology that is inefficient in the above sense may nonetheless be cost minimizing if it allows the capitalist to lower the cost of some input. This is possible in the Marxian model because the firm is not a price taker with respect to the price of labor, but rather may alter this cost through the selection of various labor extraction strategies. The most obvious case of this is the adoption of machine-paced production as a means of

<sup>21</sup>If workers could instantaneously find alternative employment, but nonetheless bore significant costs of job changing—either through moving costs, training costs not borne by their new employer, employment bonds, or job entry fees that are forfeited upon job loss, a tax levied by the government on job changers, or through any other means, or if on-the-job nonwork activities were treated as a criminal offense subject to fines or imprisonment, the attainment of full employment could not be ruled out on theoretical grounds. While possible substitutes (or complements) to the threat of unemployment are thus readily imaginable, their actual or potential relevance to the problem of getting workers to work may be questioned. First, to replace the threat of unemployment, the costs imposed must be quite substantial, considerably more than reasonable moving or training costs, and in excess of what most workers can readily borrow for payment of an employment bond. Juliet Schor and I (1983) estimate that in 1983, for example, the mean cost of job loss (roughly an after-tax estimate of  $\bar{w}^d$ ) was about one-half the mean after-tax annual income of a fully employed production worker. (This is a low estimate, as it abstracts from the costs associated with the loss of job seniority.) Moreover, the variance among individuals of the expected cost of job loss is probably quite large, due to the high variance of unemployment duration, suggesting that if we were to drop the unrealistic assumption that workers are risk neutral, the certainty equivalent of the cost of job loss might be considerably greater than Schor's and my estimates. Consideration of the social or psychological costs of unemployment—even with a generous accounting of the joys of free time—would further augment the estimate of the costs of job loss. Second, the imposition of these alternative sanctions by either employers or through the government may involve private or social enforcement costs, or other welfare losses sufficiently large to inhibit their use. Third, some otherwise promising methods of eliciting work effort other than the threat of unemployment may be considered to be socially unacceptable or politically infeasible. Even assuming that effective alternative sanctions were feasible would only modify rather than nullify my results unless these alternatives were so cost effective as to totally eclipse the expedient of paying workers more than their supply price.

increasing the intensity of labor.<sup>22</sup> In this case, costs may be lowered not only by producing more with the same inputs, but by extracting more of one of the inputs—labor—for the same price, and thus lowering the unit cost of labor. Machine-paced production may of course also be efficient. But it is simple to show that it *need not* be efficient in order to be adopted.

Capital goods may be considered to be capable of joint production, simultaneously contributing to the marketed output of the firm and producing or contributing to the acquisition of information on the work performance of the workforce. The assembly line, and even factory production itself (in contradistinction to more decentralized production methods), as well as modern information-processing systems are important cases of surveillance information-producing technologies.

The implications for efficient technical choice may be readily seen by modifying the labor extraction function to take account of this form of joint production. We now have

$$(5') \quad l^* = h[p^o(s, x), \hat{w}^d],$$

where  $x$  is the vector of inputs (per labor hour) of production equipment and intermediate goods, and  $p^o(s, x)$  is the worker's expected probability that a nonwork strategy will be detected. For some  $x$  we have  $p_{ox} > 0$  and hence  $h_x > 0$ : given the cost of job loss ( $\hat{w}^d$ ) and the level of (pure) surveillance inputs ( $s$ ), the use of larger amounts of some input in the production process will increase the amount of work done per hour by increasing the probability that a nonwork strategy will be detected, thus increasing the worker's expected cost of pursuing a nonwork strategy.

It can be seen in this case that even if all relative goods prices were optimal (in the sense that they accurately reflected relative scarcities), the familiar conditions for efficient technical choice (i.e.,  $f_x = p_x$ ) would be violated. For it will now be the case that the

profit-maximizing employer will maximize profits by observing the following condition:

$$(12) \quad f_x + f_l h_x = p_x.$$

The second term on the left-hand side reflects the contribution of a marginal increment in  $x$  to production via its contribution to the extraction of labor from labor power. (It is redundant to observe that under these conditions the relative general equilibrium prices would also not be optimal.)

The implication of this point is that a competitive profit-maximizing capitalist could choose a technology using more of both  $x$  and  $l^*$  per unit of output. This may be readily seen by noting that the isocost function slope is

$$(13) \quad dl^*/dx = -(p_x + l^* c_{lx})/c_l,$$

where  $c_{lx}$ , the derivative of the cost of a unit of effort with respect to  $x$ , is negative, and hence the numerator is not necessarily negative. Thus the isocost function may be positively sloped, leading to the possibility that cost minimization may result in the choice of an inefficient technology, namely in the rejection of a technology using less of both  $l^*$  and  $x$  per unit of output.

It might be thought that this demonstration implies that the need for surveillance inputs is somehow illegitimate and should be abstracted from in consideration of efficiency. Indeed, as we shall see in the penultimate section, the assertion that the class structure of capitalism induces a particularly high level of work resistance and hence promotes the extensive use of surveillance inputs differentiates the Marxian from the neo-Hobbesian view. But the above argument involves neither abstracting from surveillance inputs, nor considering surveillance to be a kind of false need induced through an endogenously generated disutility of labor.

Quite the contrary, pure surveillance inputs  $s$ , with an *exogenously* determined labor extraction function, provide a particularly clear case of the above argument. Consider the indicated isowork function in Figure 1 as representing an amount of work effort capable of producing one unit of output. Starting at point  $a$ , were the firm to move along this

<sup>22</sup> Edwards (1979) refers to this as "technical control" in contradistinction to "bureaucratic control" or "simple control" of the production process.

isowork locus by raising wages and cutting surveillance inputs, the cost of labor would rise and hence the profit rate would fall, but output per unit of input would rise ( $I^*$  remaining constant and  $s$  falling). This result arises because there is a tradeoff between surveillance and the wage rate in the labor extraction function, and while surveillance inputs are resource-using, the wage rate is not; hence raising wages and lowering surveillance may be efficient but not profitable. Thus cost minimization and efficiency do not coincide: the tradeoff in this case is not efficiency vs. equity, but efficiency vs. profitability.

#### IV. Divide and Rule

Central to recent Marxian research on racial and sexual discrimination, segmented labor markets, and internal labor markets is the proposition that divisions among workers may be in the interest of employers, and further that it may be in the interest of competitive noncolluding employers to discriminate among workers on the basis of ascriptive characteristics unrelated to the individual worker's ability or willingness to contribute to the production process.<sup>23</sup>

Reich, Roemer, Gintis, and others have recently proposed coherent models of discriminating competitive capitalists. The present model of the extraction of labor from labor power may be extended in a very simple way to capture the logic of these contributions.<sup>24</sup>

<sup>23</sup> This view may be distinguished from that which maintains that the cost-minimizing process renders discrimination unprofitable to the individual employer, however beneficial it might be to the employer's class as a whole, and hence that discrimination is primarily an ideological or political phenomenon whose perpetuation is explained by inertia, ignorance, or by the collective action (in the media, schools, state, or elsewhere) of those who benefit from it.

<sup>24</sup> See Reich and the previously cited references to Roemer and Gintis. This model differs somewhat from those cited in stressing the costly nature of surveillance and the cost of job loss rather than bargaining strength based on worker unity. All of the Marxian models differ from the search theory approach to the stability of discrimination in a competitive environment in that the employer is assumed to know all of the relevant worker characteristics.

We say that an employer discriminates when he or she makes different wage-surveillance offers to workers of differing ascriptive characters (race, sex, age) who are otherwise identical with respect to their productive capacities and proclivities, that is, given that we have assumed that labor services are homogeneous, identical with respect to their labor extraction functions,  $h$ . I now introduce the possibility that workers may cooperate either to render surveillance more difficult or otherwise more expensive (for example by refusing to offer information on the work or nonwork activities of fellow workers), or to reduce or withdraw labor services should the employer treat a fellow worker in a manner thought to be unjust or simply contrary to the interests of other workers. Labor services may be withdrawn either through a reduction in work effort (an outward shift in the  $h$  function), or in an extreme case through a strike.

The extent of worker cooperation, including the possibility of forming institutions such as unions, varies positively with the extent of worker unity,  $u$ . Worker unity will depend on general social conditions external to the firm, but it will also be influenced by the firm's hiring and pay policies. Where a uniform wage surveillance package is offered to all workers, for example, opportunities for joint negotiations concerning wage and working conditions will be enhanced, and divisive sentiments such as envy and invidious distinction attenuated. With distinct pay and surveillance packages offered to different workers—particularly to groups of workers predominantly composed of individuals of different race, sex, age, and other characteristics—employers are more likely to be able to bargain separately with each group to foster competition, envy, or even hostility among the distinct groups, and thus to discourage unity. For simplicity we say that unity,  $u$ , will be a negative function of a measure of wage inequality of the workforce of the firm,  $v$ .<sup>25</sup>

<sup>25</sup> Because  $u$  cannot readily be measured, this behavioral assumption cannot easily be tested. But it is strongly supported by the relevant works in labor economic and labor history. See Reich, and Edwards, Gordon, and Reich and the works cited therein.

I make an additional assumption, not necessary to my result but one which will enrich the model somewhat: let us now assume that there are some costs to the employer of replacing the worker (firm-specific training, or other), and that, for this reason, when a worker is detected pursuing a nonwork strategy, the employer may choose not to terminate the worker's employment.

In my expanded model, then, the expected cost to the worker of pursuing a nonwork strategy is

$$(14) \quad E(n) = p^o p^t \hat{w}^d,$$

where, as before  $\hat{w}^d$  is the cost of job loss,  $p^o$  is the probability of being detected should the worker pursue a nonwork activity, and  $p^t$ , previously assumed to be unity, is now the variable probability of being terminated, if detected. By the above argument,

$$\begin{aligned} p^o &= p^o(s, x, u) \quad \text{with } p_{ou} < 0; \\ p^t &= p^t(u) \quad \text{with } p_{tu} < 0. \end{aligned}$$

The labor extraction function thus becomes

$$(5'') \quad l^* = h[p^o(s, x, u), p^t(u), \hat{w}^d]$$

in which the derivative of  $l^*$  with respect to  $u$  is negative, taking account of the effects of unity on both the probability of detection and the probability of termination.

Under what conditions will the employer described in this model choose to discriminate? Assume that there are two "types" of worker, type  $i$  and type  $j$ . Why would the employer pay them different wages? It is clear at once that if the wage rates prevailing in the rest of the economy are different, or if the probability of reemployment or access to unemployment insurance is different, the optimal wage offers  $w_i$  and  $w_j$  will differ. Thus given differing external conditions, the firm will choose to offer differing wages to each type of worker. But it will be clear that the cost of a unit labor from one type of worker is less than the other, or  $c_{ij} < c_{ii}$  (assuming that type  $i$  workers are favored by higher wages and/or reemployment probabilities or access to unemployment insurance in the remainder of the economy). So the question

arises, why would the employer choose to employ any of type  $i$ ?

Assume that the employer hired no type  $i$  workers. In this case, there would be no wage inequality among the workforce ( $v = o$ ). Hiring some type  $i$  workers will yield a positive  $v$ , thus increasing  $l^*$  and possibly lowering the average cost of labor for the firm as a whole,  $c_j$ . By the same reasoning, it could be in the interest of the employer to offer type  $i$  and type  $j$  workers different wages, even if in the rest of the economy they were treated perfectly equally. Moreover, given the existence of involuntary unemployment, such a strategy would not be rendered infeasible by the labor supply choices of the group which was offered the lower wage.

A related but distinct argument for paying identical workers different wages may also be offered, if the model is extended to more than one time period. Assume initially that all workers are paid the same wage. An employer could then offer a prospective worker a two-period wage package with a low first-period and high second-period wage. The difference in the first-period wages under the equal wage and the stepped-wage package may be considered an employment bond paid by the worker to the employer which will be returned to the worker in the form of higher second-period wages, unless, of course, the worker is fired in the interim. Let the wage cost to the firm of the two packages be the same, assuming the firm intends to make good its second-period offer, and expects the worker to neither quit, nor be fired. The "less now, more later" offer will elicit more work from the worker, however, because once it is accepted and work under its terms has commenced, the cost of job loss under the terms of that package is greater, because the worker has already performed some low wage labor and has an increasingly advantageous balance of high wage labor to look forward to should he or she retain the job. In a regime of generalized stepped-wage offers such as the primary labor market in the United States, the costs of failing to cash in on later-period high wages can be considerable.

The worker may not accept the stepped-wage offer, of course, if he or she believes that the probability of getting arbitrarily fired

at the end of the first period is high. But should the worker accept the stepped-wage offer, the firm will have affected a reduction in its cost of labor  $c_l$ . As in the case of discrimination above, the fact that jobs are rationed will allow the firm to recruit labor using the less attractive stepped-wage offer.

Thus long-term contracts and internal labor markets—promotion ladders according to job tenure and unrelated to skill—may be a method of increasing the cost of job loss to the worker without increasing the wage bill, and hence an effective means of reducing the cost of labor (in effort units).<sup>26</sup>

The above explains why identical workers may be paid differently. It does not explain why discrimination exists, or why type  $i$  workers tend to be white, male, and neither very young nor very old. But it does present one possible argument for the reproducibility of discrimination and internal labor markets in a competitive capitalist economy.

#### V. Neo-Hobbesian and Marxian Models

It may well be objected that while the labor extraction model provides an internally consistent analysis of involuntary unemployment, inefficient technical choice, and discrimination in a competitive equilibrium, any negative normative connotations would be misplaced, for these undesirable outcomes might be intrinsic to *any* system of production, irrespective of the social structure in

which it is embedded. Indeed this is precisely the implication of what I have termed the neo-Hobbesian models of the production process.

Malfeasance is to the neo-Hobbesian models what class conflict is to Marxian models. The key difference between the two is this: malfeasance is a universal human proclivity—in this case based on the inherent nature of work as a disutility. By contrast, class conflict in the labor process of a capitalist economy is the result of a specific and mutable set of social institutions; the conflict over work intensity being *at least in part* the consequence of the particular organization of work and the resulting alienated nature of labor.

Samuelson's statement cited at the outset—while based on a Walrasian model—reflects the spirit of the neo-Hobbesian models as well, for it is consistent with the view that the form of the class relationship imparts nothing of importance to the production process.

Can the neo-Hobbesian position be sustained? Can the Marxian problem—class conflict over the extraction of labor from labor power—be reduced to the general problem of malfeasance? Differing ideological connotations aside, is the extraction of labor from labor power simply another way of addressing the universal problem of "shirking"?

Concern with the general problem of reconciling individual self-interest and collective rationality is hardly new, dating back at least to Hobbes. That the regulation of self-interest through the market provided a solution to the Hobbesian problem was suggested metaphorically by Mandeville during the eighteenth century and developed fully by Walras and by twentieth-century welfare economists. If all economic interactions are contractual exchanges, the conflict of self-interest and collective rationality is capable of resolution, or at least substantial attenuation.

But, as economists of all persuasions now recognize, not all economic interactions are exchanges. Coase's conception of the firm, as a command economy of nonexchange relations, is a necessary but possibly troublesome addition to any analysis of a specifically capitalist economy characterized by an

<sup>26</sup>From quite different perspectives, a similar argument has been suggested by Edwards and by Lazear. The argument is quite distinct, however, from models based on search theory and screening costs, in which the employer has an interest in retaining the worker (because of hiring costs). See, for example, Okun. The post-World War II emergence of long-term contracts and internal labor markets as characteristic of a major segment of the U.S. economy may be attributable in part to their labor extraction cost-saving aspect, to the historically low rates of unemployment in the postwar period, and to the apparent decline in the cost of job loss associated with a spell of unemployment. Further, as Lazear has pointed out, the labor extraction advantages of long-term stepped-wage offers may help explain the otherwise anomalous phenomenon of returns to job tenure significantly in excess of any empirically compelling estimates of productivity enhancement through generalized on-the-job learning. See James Medoff and Katherine Abraham (1980).

employment relation. Strikingly, the Coasian view of the capitalist economy as a multiplicity of mini-command economies operating in a sea of market exchanges is radically different from the Walrasian foundations of welfare economics, and superficially indistinguishable from the Marxian view.

The question obviously arises, then, as to the compatibility of the Coasian insight (command) and the Mandevillian solution to the Hobbesian problem (markets). Are the command relations of the firm a rational solution to the problem of the coordination of individual and group rationality? Or are they, in some sense, a market failure attributable to the successful pursuit of the interests of those who command the firm? This is the central issue dividing the neo-Hobbesian from the Marxian analysis.

Coase, basing his concept of the firm on the notion that command relations supercede market relations when the transactions costs of markets exceed the analogous costs of command and nonmarket coordination, initiated a literature which affirmed the efficiency of the hierarchical structure of the firm.<sup>27</sup> Because malfeasance is no more than an expression of the natural self-interestedness of human beings, the cost of policing malfeasance cannot be considered evidence of a failure of markets. The logic of this position can be illustrated within the terms of the Marxian model.

Let us make the (neo-Hobbesian) assumption that the labor extraction function is given by human nature. People's attitude towards work—broadly, the disutility of labor—is unrelated to the social institutions that govern the process of work. In this case, the extraction function must be considered to be exogenous, not only to the firm but to the society as a whole. Hence the various employer strategies and their results must be considered to be little more than a consequence of the (possibly lamentable but ineradicable) human tendency to avoid work. A society might nonetheless choose to discourage discrimination, to minimize involun-

tary unemployment, or to discourage the use of surveillance equipment or personnel, but they would do so only at the cost of choosing to permit a higher level of what the neo-Hobbesian literature terms free riding or shirking, and consequently a lower average level of output per hour of labor.

But the assumptions required to sustain the neo-Hobbesian view are exceptionally restrictive and implausible. We have seen in the analysis of capitalist technology that even with an exogenously given labor extraction function, the choice of technology—including the level of surveillance—which is profit maximizing will not in general be efficient: it generally will be dominated by some other less profitable and less surveillance-intensive combination of inputs.<sup>28</sup>

Perhaps more fundamentally, the assumption of an exogenous extraction function appears to be quite arbitrary. If the organization of the work process and the principles determining the distribution of the net revenues arising therefrom influence workers' attitudes towards work and hence are among the determinants of the extraction function, the neo-Hobbesian conclusions are considerably altered. In this case, there may exist some alternative set of arrangements in which a bargain could be struck in which at least one of the participants was better off and none worse off. A possible argument may be illustrated. Rewrite the labor extraction func-

<sup>27</sup>The recent literature was initiated by Alchian and Demsetz.

<sup>28</sup>Because the efficient (less surveillance-intensive) technology is less profitable it might be objected that while the neo-Hobbesian position is faulty on static efficiency grounds, a dynamic efficiency perspective, taking account of optimal levels of investment and the relationship of profits to investment, would salvage their view. But this is not the case unless it is also assumed that the current levels of investment are at or below the optimal level and further (and dubiously) that a reduction in the profit rate is necessarily associated with a decline in investment. To the extent that capitalists consume rather than invest their profits (or invest them in other economies), a decline in the profit rate does not require a reduction in the level of investment, even if the economy is operating at the level of potential output. Of course, given the institutions that define the capitalist economy, such an effect is likely to result, but it is hardly reasonable to take as given the institutions which are themselves under evaluation.

tion as

$$(5''') \quad l^* = h(i, s, \hat{w}^d, u, x),$$

where  $i$  is a vector reflecting the general institutional environment. If it could be shown that in an environment which workers perceived to be more fair, or more consistent with their self-respect, for example, they would choose to expend more effort for any given employer strategy, then it is a simple matter to demonstrate that the initial outputs could be produced with unchanged levels of labor effort in production and using less surveillance labor.<sup>29</sup> In Figure 1, the transformed institutional environment (the change in  $i$ ) would be reflected in an inward shift in the isowork loci such that the initial amount of work could be extracted with a reduced  $s$ .<sup>30</sup> The newly released surveillance labor could then be employed producing goods representing a net addition to the total product, achieved without increasing total labor hours worked and/or workers' efforts per hour.

The above argument draws directly on the third basic characteristic of the production process in the Marxian model, the joint production of commodities and workers or the endogenous nature of workers' preferences. The attitude towards work is not, according to this principle, simply a manifestation of human nature, but in part the result of the social institutions in which the production process takes place.

In the production of workers, of course, other institutions—schools, the family, political organizations, and the like—assume a critical importance. The structure of these institutions is, however, strongly albeit indirectly influenced by the structure of the production process.<sup>31</sup> Moreover, the structure of

the production process itself undoubtedly has direct effects on attitudes towards work. A more democratic structure of decision making and a more egalitarian distribution of the firm's net revenues, for example, might both reduce the incentive to pursue nonwork activities and heighten the cost of so doing by enlisting fellow workers as more ardent enforcers of the pace of work, or more willing cooperators with the surveillance system.<sup>32</sup>

The neo-Hobbesian's normative position thus seems dubious on two grounds: the discrepancy between profitability and efficiency, and the endogeneity of the labor extraction function. If the social nature of the labor extraction function is conceded and, further, if the feasibility of forms of social structure and work organization conducive of lower levels of work resistance or higher levels of work motivation is accepted,

---

William Lazonick (1978, 1981). Lazonick concluded, "Hence it can be argued that not only the institutional transformation of the capitalist enterprise but also, and perhaps more fundamentally, the institutional transformation of the larger society was required to stabilize the capital labor relation in the mass production industries" (1981, p. 36).

<sup>32</sup>Why are the potential gains to such an alternative form of work organization not sufficient to bring such worker-based enterprises into being and to assure their success in the competitive struggle with more hierarchically structured capitalist firms? If workers' attitudes toward work were determined solely and instantaneously by the work environment in which they worked, and if credit were readily available on terms no worse than those available to capitalist firms, any group of workers could form a co-op and reap the benefits of lessened surveillance. Both assumptions are highly questionable. To the extent that attitudes toward work are determined by an entire nexus of social institutions which change slowly, the opportunities for the atomistic movement towards a less socially irrational form of production are quite limited. Perhaps more important, because workers' own assets are not extensive, their access to credit is limited or costly by comparison to that enjoyed by the owners of firms. (It matters little for the issues treated here whether the different terms of credit available to capitalists and workers reflect rational profit-maximizing behavior by lenders or an imperfection in the credit market.) And it might be added that, perhaps for some of the reasons outlined in this paper, and despite the obstacles outlined in this note, the last decade has witnessed a substantial growth of workers' co-ops and worker-managed firms in the United States.

<sup>29</sup>There seems to be considerable evidence that this is the case. See, for example, Raymond Katzell et al. (1975).

<sup>30</sup>A simple reduction of  $s$  would not be optimal, of course, but this is immaterial to my argument.

<sup>31</sup>The influence is mutual, of course, schools and families influencing the structure of production as well as conversely. See, from very different perspectives, my book with Gintis (1976), Melvin Kohn (1969), and

or, if the possible nonoptimality of the competitively determined profit rate is admitted, the command relationships within the firm and the associated patterns of involuntary unemployment, technical choice, and discrimination must be viewed as market failures rather than simply as unavoidable transactions costs. Moreover, because of the importance of the labor input in the production process, the quantitative importance of this source of market failure may overshadow the more commonly recognized environmental and other externalities.

## VI. Conclusion

The model of the production process based on the extraction of labor from labor power thus provides an internally consistent micro-economic theory capable of supporting some of the most fundamental general propositions in Marxian economics concerning the reserve army of the unemployed, the determination of the profit rate, discrimination, and the irrationality of the organization of work and technology. The above arguments do not, of course, establish the superiority of the Marxian model. Nor do they provide any indication that the Marxian model is capable of generating plausible empirical accounts of such phenomena as movements in the unemployment rate, the profit rate, the structure of discrimination, or technical choice.

However, a significant amount of empirical work along the lines outlined above has been done, some of it with quite successful results. For example, econometric models of postwar U.S. productivity growth, the profit rate, Tobin's  $Q$ , and strike activity using an empirical measure of the cost of job loss,  $\hat{w}^d$ , have generated highly significant and robust estimates consistent with the expectations of this model.<sup>33</sup> Historical studies of technical choice and work organization based on the extraction of labor from labor

power have produced compelling accounts of otherwise anomalous patterns of technical change. (See Lazonick, 1982, and Marglin.) And econometric studies of the distributional impact of discrimination have produced results quite consistent with the divide and rule interpretation. (See Reich.) None of these is alone decisive, but taken together they do suggest that the Marxian model offers a promising direction for empirical investigation.

# The Validity of Profits-Structure Studies with Particular Reference to the FTC's Line of Business Data

By GEORGE J. BENSTON\*

The simple proposition that consumer-damaging collusion is more likely to occur when there are fewer competitors has given rise not only to legal restrictions of economic activity thought to restrict output, but also to an enormous amount of empirical work attempting to relate market concentration to the exercise of monopoly power.<sup>1</sup> Most such studies measured market structure by an index of concentration (for example, four-firm concentration or Herfindahl) and performance by accounting profit (for example, net profit divided by assets) or price-cost margins (sales less direct costs divided by sales). From the positive, statistically significant correlations often found between greater concentration and profit (with other factors presumably accounted for), some researchers conclude that increases in concentration are anticompetitive and that concentration, therefore, is bad.

The concentration-profits studies have been criticized essentially on two grounds. One is that the positive relationship is not indicative of collusive behavior. In particular, Oliver Williamson (1968), John McGee (1971), Harold Demsetz (1973, 1974), and Sam Peltzman (1977) point out that higher profits could result from efficiencies experi-

enced by large firms, which resulted both in greater market shares and high levels of concentration. Analytical arguments show that higher profits logically follow as much from lower costs that are associated with higher levels of concentration, as from collusion-determined higher prices. Some empirical evidence that supports this belief is presented by Demsetz, Peltzman, and Bradley Gale and Ben Branch (1982). However, their findings have been contested on the grounds that the data used are biased or inadequate, or that the researchers have not demonstrated that the observed higher-profits/greater-concentration relationship was caused by lower costs.<sup>2</sup>

The second criticism is that available data provide an inadequate basis for such conclusions. The concentration numbers are based, usually, on industries defined by the Commerce Department's Standard Industrial Classifications (SIC). The SIC definitions tend to be supply (production) rather than demand determined, include nonhomogeneous products, and exclude sales of similar products that are included in different SIC groups or are imported. The profit data are taken from accounting reports that provide poor measures of economic values. Weiss (1974) describes many of these problems. However, he does not believe that these shortcomings invalidate the studies. As Weiss (1979) concludes:

I argued that the crudeness of the concentration data, the increasing diversification of firms, and many distortions

\*Professor of Accounting, Economics, and Finance, Graduate School of Management, University of Rochester, Rochester, NY 14627. I am indebted to Armen Alchian, Stanley Liebowitz, and the members of economics workshops at the University of Western Ontario and the University of Rochester Graduate School of Management for valuable suggestions.

<sup>1</sup>See Leonard Weiss (1974) for a review of 46 papers, a presentation of a 47th, and a footnote mention of 8 more, which he notes excludes studies on banking markets. For a review of 15 additional studies on banking markets, see my article (1973). Weiss (1970) also reviews many of these studies but does not find them largely inadequate, as I do. Since the time of these surveys, many more similar papers have been published, of which a few are reviewed below.

<sup>2</sup>See F. M. Scherer (1979b), who shows how the industry output and price statistics used by Peltzman are likely to be biased. Scherer argues that product innovations rather than production efficiencies are causally related to higher profit rates. He does not provide similar (or any) evidence showing that the higher profits are due to collusion.

in accounting profits all bias the observed relationship between concentration and profits towards zero. Because of these biases, I argued that the effect [of a significant positive relationship] was probably understated when observed, and that it might well have been present when it was not detected. [pp. 1106-07]

Largely as a consequence of these problems (particularly the increasing diversification of large companies that made their reported profits and other data difficult, if not impossible, to link with measures of market concentration), the Federal Trade Commission (FTC) designed and implemented a large scale program to gather detailed data from large companies by lines of business (*LB*).<sup>3</sup>

Originally, the program sought to collect data from some 2000 companies on their revenues, expenses, and assets, allocated to 357 lines of business. After vigorous protests, culminating in an unsuccessful 1975 challenge in the Washington, D.C. District Court, the program was scaled back somewhat, and 450 of the largest industrial companies were required to file reports on 267 FTC-designated lines of business (that follow the SICs) for 1974 through 1977. (Partial reports also were filed for 1973.) These data are much more extensive and detailed than have ever been collected by a public agency. Through September 1983, the FTC published five *Statistical Reports*, and forty papers and reports based on the data have been written by its staff and outside economists.<sup>4</sup> Thus, there is a substantial basis on which the usefulness of the program, and of profit-structure studies in general, can be judged. Considering the large number of observations, the detail, the cost of the data, and the qualifications of the

economists who used them, an analysis of the inputs and outputs of the *LB* program can serve as a general critique of the very large body of empirical work that is based on company accounting numbers and data classified by SICs.<sup>5</sup> It also can put into context the large number of studies and other analyses that have been and are likely to be generated from the FTC's *LB* data, since these numbers are on computer tape and are being made available to approved researchers and published in tabular form by the FTC.

### 1. The *LB* Program's Purposes

The first *Statistical Report* published under the FTC's *LB* program reiterates the purposes for which *LB* data were to be used.<sup>6</sup> According to the FTC staff, "The Line of Business Program is designed to elicit information vitally needed in evaluating industry performance" (FTC, 1981a, p. 2). These data, they say, will serve the following purposes:

1. *Antitrust Enforcement*: "Knowledge of industry performance is essential to efforts of the Commission to direct its activities towards industries where poor performance suggests the need for more detailed investigation and possible enforcement action."

[p. 3]

2. *Allocation of Private Sector Resources*: (a) "Managers and directors of corporations will be able to evaluate the performance of their own enterprises against industry averages;" (b) "investment analysts and investors are likely to find *LB* reports useful in evaluating the prospects of particular industries."

[p. 4]

3. *Aid for Economic Research in Industrial Organization*: "And, like economists within the FTC, outside scholars

<sup>3</sup>A resolution of the alternative (efficiency) explanation of the data might also have been a goal, but it was not mentioned in the FTC's Statements of Purpose. See my article (1979, pp. 61-65) for a review of these statements. Also see Federal Trade Commission (1981a, pp. 1-7), which repeats the purposes of the program and does not explicitly mention the efficiency-profits-structure hypothesis.

<sup>4</sup>At least 19 of these have been published or accepted for publication.

<sup>5</sup>From 1978 through 1981, 112 econometric studies in industrial organization were published, according to a review of the *Journal of Economic Literature* and the Index of the *Harvard Business Review* (William Long et al, 1982, p. 141; the papers are listed in their appendix D).

<sup>6</sup>See FTC, 1981a, pp. 1-6.

will use the Line of Business aggregates as a basic data source for advancing the frontiers of knowledge in the field of industrial organization." [pp. 4-5]<sup>7</sup>

It is clear that the *LB* program requires numbers that adequately reflect the desired *economic* market values. Moreover, to be useful for the purposes delineated, the economic market values would have to separate the present values of gains from monopoly power from those due to other causes, such as luck or disequilibrium.

## II. The Usefulness of the FTC's Line of Business and Similar Data for Evaluating Economic Performance

The validity of company accounting data for economic analyses, such as those to which the FTC's *LB* program is directed, would be best determined with tests of prediction. However, these require a measure of "true" economic value, which (to my knowledge) is not available. Hence, two procedures (followed in Sections II and III) are employed. In Section II, accounting numbers, as they are reported to users of published financial statements and to the FTC, are analyzed a priori to determine the extent to which these numbers appear to reflect economic market values. This exercise is undertaken because, as is discussed in Part A, accounting biases are unlikely to be randomly distributed with respect to most of the variables of interest for testing structure-performance hypotheses. The analysis of accounting biases that follows in Part B shows why researchers would find it very difficult, if not impossible, to measure and adjust for the biases, even

were much firm-specific information available. The empirical procedures employed by FTC economists to overcome two problems, overhead allocation and transfer pricing, are considered here. In Part C, the degree to which the data are contaminated and incomplete, given the FTC's (SIC) definition of industries, is assessed.<sup>8</sup> Some evidence supporting the concerns about the data is presented in Part D. In Section III, the application to hypothesis testing of the accounting numbers collected by the FTC is evaluated, to determine whether the researchers were able to overcome the severe shortcomings of the data that are delineated in Section II.

### A. The Interaction of Accounting Measurement Biases and Measures of Performance

The analysis presented below shows that differences between accounting measures and economic market values are likely to be significant and very difficult (in many important instances, impossible) to determine. However, were they randomly distributed with respect to variables of interest, the result would only be noise or possibly spurious correlations. It is doubtful, though, that such randomness occurs, for the three reasons outlined next.

First, several studies have shown that firms' choices of accounting procedures are functions of their size, propensity to be regulated, management profit-sharing plans, debt covenants, and tax situation. For example, Ross Watts and Jerold Zimmerman (1978) find the larger firms and those more likely to be regulated tend to choose accounting methods that result in lower reported profits. Robert Hagerman and Mark Zmijewski (1979) find that systematic differences in the accounting

<sup>7</sup>In the FTC's previous releases, which also stress these purposes, mentioned additionally are improvements in the government's efforts to control inflation and unemployment, aids to small business firms and to buyers and sellers of goods, facilitation of labor unions' bargaining by providing them with information on profits, and information to farm groups that will help them in dealing with suppliers and processors. For references to the relevant documents and critique of the aims of the program, see my article (1979). Also see William Breit and Kenneth Elzinga (1981). For an opposing view, see Scherer (1979a).

<sup>8</sup>The poor conformance of four-digit SIC-defined markets (which the FTC uses to define lines of business) to homogeneous industries is discussed and demonstrated by Weiss (1974, pp. 194-96), Betty Bock (1975), and my article (1979, pp. 66-78), among others. (See fn. 49 below for a very brief description of five such "industries.") Therefore, though this problem is severe, it is not analyzed further here. An additional bias is the restriction of the program to large firms.

methods adopted are related to whether the firms are management controlled or owner controlled. Robert Holthausen and Richard Leftwich (1983) report that the presence of debt covenants affected the accounting procedures used. Unfortunately for researchers who would use accounting data, these biases need not be constant. For example, if a firm is in a steady state, profit understated in an earlier year results in an overstatement in a later year, *ceteris paribus*. Other combinations of effects can occur, as is discussed below. Thus, even if these biases were known and identified with specific firms, the researcher must also deal with the effects of past decisions to adopt alternative accounting procedures.

Second, alternative accounting procedures need not be consistently applied by all firms in an industry. This is likely to be a greater problem when industries are defined by SIC codes. It is exacerbated further when industries are formed by aggregating the FTC-defined *LBs* of different firms, firms with accounting practices determined by their original industry status. For example, Eastman Kodak may have adopted firm-wide accounting methods that are appropriate for a film and camera maker, but its chemical activities are aggregated by the FTC with those of, say, Union Carbide which may use methods appropriate for a chemical manufacturer that specialized in batteries. Additionally, centralized firms that do not allocate expenses, assets, and capital to product lines may be compared with decentralized firms. As a consequence the former report higher price-cost margins ( $P/S$ ) and returns on assets ( $P/A$ ), *ceteris paribus*, where costs are defined as allocated expenses. Furthermore, to the extent that accounting biases are industry related, observations from different industries cannot be compared or pooled without the differences being adjusted for.

Complicating matters further, the FTC's rules permit firms leeway in assigning their data to specific SIC codes. Consequently, accounting differences among a changing sample could be responsible for the considerable changes (reported in Part D below) in the aggregate industry ratios published by

the FTC in its *Statistical Reports* (1981a,b; 1982). These are the data that will be available to non-FTC researchers and other users. The potential for drawing incorrect inferences from these data would appear to be considerable.

Third, there is reason to believe that accounting mismeasurement of economic market values is associated with some commonly used measures of company performance. For example, a concentrated industry may be one in which only a relatively few firms compete because a large investment in fixed assets is required. If the values of these assets are understated, perhaps because they are recorded at amounts that do not reflect inflation, depreciation also is understated. Consequently, such measures as  $P/S$  and  $P/A$  will be positively associated with concentration, *ceteris paribus*. Similarly, if a few companies dominate an industry because they previously invested in intangibles (such as patents, industrial processes, marketing networks, and advertising), the current reported  $P/S$  and  $P/A$  will be overstated. Thus market share and profit rates will be positively associated, *ceteris paribus*, though not as a consequence of market power. Indeed, if the amounts expended on intangibles were correctly accounted for, it might be that the acquisition of a large market share was a negative present value investment. Unfortunately, this bias need not be stable. For example, the reported  $P/S$  of a growing company could be understated. (These possibilities are discussed further in subsection B1.)

As a further example, it may be that executives who manage lines of business with large market shares are compensated, in part, with a share of accounting profits. In a particular year, they (and their bosses) may find it desirable to show larger profits. Or companies with *LBs* that show large market shares may be those that experienced a surge in demand, perhaps because the prices of substitutes increased. If these companies allocated overhead to product lines as a fraction of direct costs, their product costs would not increase as much as their revenues. Hence  $P/S$  and  $P/A$  would be positively associated with higher market shares, *ceteris paribus*.

But the relationship would not be as positive had they allocated overhead according to sales dollars. In either event, a measured association between profits and market shares would reveal nothing about market power or efficiency.

Many more examples could be given to explain measured relationships between accounting profits and concentration or market share. Therefore, researchers who would use company accounting data should at least attempt to adjust for biases or show that these are not important. On the first point, the following analysis demonstrates that the required adjustments are very difficult or (in many important situations) impossible to effect. Though some researchers who use accounting numbers profess awareness of the inherent biases, they do not seem to realize just how complex the situation is.

#### B. *Company Accounting Data and Economic Market Values*

The extent to which accounting data differ from economic market values is presented in subsection 1. The usefulness to companies of these data, despite their considerable divergencies from economic market values, is explained in subsection 2.

1. *Divergencies of Accounting Data from Economic Market Values.* For present purposes, only the generally most important sources of divergencies are considered.<sup>9</sup> These include: (a) the values of long-lived tangible assets and their depreciation or depletion over time; (b) the value and amortization of intangible assets (for example, advertising and research and development); (c) inventory values and the cost of goods sold; (d) allocation of common and joint costs to lines of business; and (e) intrafirm transfers among lines of business. For each, the reasons for the divergencies are delineated first, followed by an evaluation of the extent to which the reported numbers can be adjusted to approximate economic market values and the

effect of the remaining biases on two commonly used measures of economic performance, the profit rates on sales and assets. The conclusions of the analysis are summarized in Table 1 and an analytic estimate of the cumulative impact of the accounting biases is given in subsection (f).

#### (a) *Long-Lived Tangible Assets and their Depreciation or Depletion Over Time.*<sup>10</sup>

*Accounting Procedures.* Accountants do not attempt to record, initially, an asset's economic value to a firm, but, rather, the amount paid for it as measured in objectively determined monetary units (market value). An asset's economic or present value (value in use) to the firm should be greater than or equal to its market value (value in exchange), since otherwise the asset would not have been purchased. The difference could be due to nonacceptable (for example, illegal monopoly power) or acceptable (for example, specialized use of resources) rents. Neither is recorded at the time of the transaction.

Where an asset is constructed rather than purchased, the recorded amount is likely to understate its competitive market value, since the seller's selling and administrative costs and total cost of capital rarely are recorded. But an asset is never capitalized (recorded as an investment) at more than its recorded cost, and, when the asset could have been purchased at less than the amount expended to make it, accountants charge the excess to expense (the conservative accounting bias).

Understatements of initial asset values are particularly serious for extractive assets. When these assets are fortuitously discovered, at most only the amounts expended for the successful discovery are capitalized. In other cases, the successful efforts method of accounting (used by most larger natural resource producers) capitalizes only the direct cost of discovering and developing successful wells and mines. The amounts spent for unsuccessful efforts are written off (expensed) as current expenses, despite the fact that successful ventures usually are accompa-

<sup>9</sup>For a much more detailed and differently structured and directed analysis, see my article (1982).

<sup>10</sup>The discussion in this subsection applies generally to the following subsections. Hence it is relatively long.

TABLE 1—THE EFFECT OF SOME DIVERGENCIES BETWEEN ECONOMIC VALUES AND ACCOUNTING NUMBERS ON THE RATIOS OF PROFIT TO SALES ( $P/S$ )<sup>a</sup> AND PROFIT TO TOTAL ASSETS ( $P/A$ )<sup>a</sup>

	Initial Period		Later Periods	
	$P/S$	$P/A$	$P/S$	$P/A$
Capital Gains—One Time				
Initially recorded assets and increases in present values	<i>UU</i>	<i>U</i>	<i>O</i>	<i>OO</i>
Capital Gains and Overdepreciation—Multiple Events				
Stable (uniform distribution of events)			<i>N</i>	<i>O</i>
Declining			<i>O</i>	<i>OO</i>
Growing			<i>U</i>	<i>?</i>
Expected Inflation	<i>N</i>	<i>N</i>	<i>O</i>	<i>OO</i>
Unexpected Inflation	<i>?</i>	<i>?</i>	<i>O</i>	<i>OO</i>
Intangible Assets				
Stable (current expenditures equal depreciation)			<i>-</i>	<i>O</i>
Declining			<i>O</i>	<i>OO</i>
Growing			<i>U</i>	<i>?</i>
Cost of Goods Sold and Inventories				
Prices increasing steadily:				
Last-in, First-out			<i>N</i>	<i>O</i>
First-in, First-out			<i>O</i>	<i>O</i>
Prices decreasing steadily:				
Last-in, First-out			<i>N</i>	<i>U</i>
First-in, First-out			<i>U</i>	<i>U</i>
Overhead allocations among products			<i>?</i>	<i>?</i>
Allocation of Joint and Common Costs and Assets to <i>LBs</i>			<i>?</i>	<i>?</i>
Intrafirm Transfers Among <i>LBs</i>				
Contamination due to Assignments to <i>LBs</i>			<i>?<sup>b</sup></i>	<i>?<sup>b</sup></i>
Transfers priced at other than market			<i>?<sup>b</sup></i>	<i>?<sup>b</sup></i>

Notes: *U* = understated; *UU* = very understated; *O* = overstated; *OO* = very overstated; *N* = not affected; *?* = bias unknown.

<sup>a</sup>Profit is before interest and income taxes.

<sup>b</sup>Probably not very great on average.

nied by unsuccessful ones. Even companies that use the full-cost method (under which amounts incurred for all discovery efforts are capitalized) expense many development costs.

Once the tangible assets have been acquired, the amounts recorded as asset values are expensed over the expected economic life of the assets. The tax regulations usually permit a faster write off, which may also be used for book (reporting) purposes. But a book method may be adopted that yields currently higher reported net income. In any event, the depreciation method chosen is not designed to measure the user cost of the assets—the change in the asset's present values—in part because these calculations are too difficult to make, and in part because the

accountants who must attest to the numbers would find such calculations uncomfortably subject to manipulation.

The recorded numbers also are not adjusted to reflect changes in the capital values of the tangible assets. Such changes could occur as shifts take place in the supply and demand for the assets, the factors used with the assets for production, and the goods produced.<sup>11</sup> When the changes are due to monopoly power or collusive pricing, the

<sup>11</sup>For example, the 1970's increase in the market price of oil increased the values of oil and gas reserves, substitutes such as coal, and fixed-price contracts to purchase these resources.

economist interested in these events would not want the values recorded as ordinary assets, since all firms then would be measured as earning zero profits. Therefore, the reasons for the change in values would have to be specified and their effects measured.<sup>12</sup> In any event, the accounting values are not changed.

The monetary values of assets also change as the purchasing power of money changes. While estimates of the effect of general price level changes now appear in the published statements of large companies, usually by the application of indices, these adjustments are not often made a part of a company's accounting system and individual asset accounting numbers are rarely changed. Furthermore, current values are not recorded, largely because the cost of such adjustments is greater than their value to most companies.

The magnitudes of the divergences between accounting numbers and economic market values cannot be determined.<sup>13</sup> An estimate, perhaps, could be made if one could obtain estimates of the current market values of individual assets. Even then, the assets' economic (present) values to the firm would not be measured, nor would the extent to which the present values are due to presumably unacceptable (for example, collusive pricing) or acceptable (for example, entrepreneurial skill) behavior. Furthermore, market-revealed values are unlikely to occur for most user-constructed assets. Even general adjustments in the magnitudes, perhaps with some index, would require detailed information about purchase dates, current

equivalents in terms of production, and the economically correct depreciation procedure to be applied. Such knowledge is impossible or very expensive to obtain.

*The Effect of the Biases on Measures of Economic Performance.* Although there is no practical way to convert accounting asset values and depreciation to economic values or to separate the causes of changes in values, those who want to use these numbers claim they could be useful if the direction and rough magnitude of the biases could be stated. But, as the following analysis shows, the effect of the biases on two commonly used ratios—operating profit to sales ( $P/S$ ) and operating profit to total assets ( $P/A$ )—is not determinable.<sup>14</sup>

As noted, increases in the value of long-lived assets are not recorded, resulting in understated profit and asset values. Consequently  $P/S$  and  $P/A$  are understated (assuming  $P/A$  is less than 1.0). Subsequently, profit and  $P/S$  and  $P/A$  are overstated, since depreciation on the higher unrecorded asset value is not recorded, and the asset remains understated. Unrecorded decreases in assets values have the opposite effect.

The effects become more complicated when the initial events and changes in asset values occur more than once, as is likely. Even if the events occurred uniformly over time, and

<sup>12</sup>The effect of monopoly on asset values could be (and has been) measured by relating changes in the market value of assets to changes in laws or firm behavior (for example, mergers) that are hypothesized to result in monopoly. These studies include taxicab licensing, stock exchange regulation, and lawsuits filed by the Department of Justice. None of these studies use accounting data. See G. William Schwert (1981) for references and a discussion of the methodology.

<sup>13</sup>Some economists (such as James Buchanan, 1969, and others whose essays are reprinted in Buchanan and G. F. Thirlby, 1973) believe that economic values (particularly costs) cannot be measured conceptually, since they depend on subjective evaluations of alternatives.

<sup>14</sup>See Ezra Solomon (1970) and Thomas Stauffer (1971) for formal proofs. Franklin Fisher and John McGowan (1983) show that the divergence between accounting and economic rates of return are likely to be nonpredictable and nontrivial. Gerald Salamon (1973) criticizes researchers who attempted to relate the firm accounting rate of return ( $P/A$ ) and internal rate of return ( $IRR$ ) by assuming that the firm  $IRR$  is equal to the  $IRR$ s of the firm's projects. Salamon shows that "...if the growth rate in gross investment ( $g'$ ) is greater than or equal to the  $IRR$  of firm projects ( $r'$ ) then the  $IRR$  of the firm is not equal to the  $IRR$  of firm projects; and in fact, the  $IRR$  of the firm is not even defined" (p. 301). Salamon (1985) also shows that an approximation to firm  $IRR$  derived from net cash flows is not significantly related to firm size, while  $P/A$  is significantly positively related. The measure he employs, though, is based inter alia on an assumed constant growth rate in gross investment and on exponentially decaying (or growing) project cash flows. He warns: "Whether the measurement error from this source [the assumed cash flows] is large or small, systematic or random is pure conjecture at this point."

the effects on profit washed out, assets would continue to be understated, and  $P/A$  would be overstated (assuming unrecorded capital gains). But if the events diminished over time, perhaps because of a decline in growth of the company or in relative prices, unrecorded depreciation probably would exceed unrecorded capital gains. Hence profit would be overstated. The cumulative understatement of assets (which would not be removed until disposal of the assets) would result in a greater overstatement of  $P/A$  than in  $P/S$ . But if the company were growing or relative prices were increasing, unrecorded capital gains probably would exceed the unrecorded depreciation of past unrecorded capital gains. Thus  $P/S$  would be understated. The effect on  $P/A$  is uncertain, since both the numerator and the denominator of the ratio are understated.

The effect of general price level changes is different because expected changes do not give rise to economic income or expense. But if the recorded nonmonetary asset amounts are not changed to reflect the current purchasing power of the dollar, an expected inflation results in understated assets and overstated profit (since depreciation is understated). Therefore, with respect to nonmonetary assets,  $P/S$  is overstated and  $P/A$  even more so. Interest income and expense also are overstated since they include a return on capital. (If the interest expense overstatement were large enough, which is doubtful,  $P/S$  could be understated.) Where the inflation is unexpected, though, the company realizes an unrecorded capital loss or gain if it holds nominally denominated assets or liabilities. Thereafter, its interest income, interest expense, depreciation, and assets are understated. The effects on  $P/S$  and  $P/A$  thus depend on the extent to which it holds nominally denominated assets and liabilities. If the unrecorded capital gains exceed the capital losses, the first-period  $P/S$  is understated;  $P/A$  is understated if the unrecorded gains were large enough. In subsequent periods,  $P/S$  and  $P/A$  are overstated (unless the unrecorded interest income is large enough).

While these biases are generally as specified, the magnitude of the effect varies with several factors. Profit rates and rates of re-

turn of companies with longer-lived assets are more affected than those with shorter-lived assets. The amounts invested in long-lived compared to other assets similarly affects the bias. Profit rates are overstated more for rapidly growing than for slowly growing companies. The methods used by the company to depreciate or deplete its assets (for example, straight-line, sum-of-the-years' digits, double declining balance, or units of production) also affects the bias. The times at which assets yield cash flows and the relevant discount rate also affect the difference between the economic profit and rate of return and the accounting numbers. Furthermore, the extent to which the initial period effects occur discontinuously affects the bias.

As is explained above (and summarized in Table 1), except in growth situations the bias in the initial period is the reverse of the bias in subsequent periods. Hence, a large enough change in one period can reverse the sign of the continuing effects of previous periods. In general, then, there is no way to know the sign of the difference between the accounting numbers and economic market values. But the differences are likely to be quite large unless the amount of long-lived tangible assets is relatively small, even without inflation. With inflation, and the nonadjustment of accounting numbers (which especially affect long-lived assets purchased at different price levels), the biases are likely to be considerable. Indeed, a sufficiently high inflation would swamp the other sources of divergence between accounting numbers and economic market values. At the least this means that companies with more tangible assets and assets that are longer lived are more likely to overstate profits and rates of return on assets. In the absence of this overwhelming inflationary effect, the direction of the bias cannot be stated a priori, nor does there appear to be any practical way to adjust the reported  $LB$  and other company accounting data to reflect desired economic market values.

#### (b) *The Value and Amortization of Intangible Assets.*

*Accounting Procedures.* The amounts spent for intangible assets—such as advertising,

goodwill, research and development, and employee training—are recorded as current-period expenses in accordance with the “generally accepted accounting principles” of the Financial Accounting Standards Board. Although a large portion of these expenditures clearly results in assets, the amounts are not recorded as such because the present values of the resulting assets are difficult to measure objectively, and managers could use the estimates to manipulate reported profits and assets. Even when estimates were made objectively, the likelihood that they would turn out to be wrong is considerable. Subsequently, even honest estimates could appear to have been deliberately misstated to fool users of the company’s financial statements. To protect the independent auditors who attest to the statements, and as a means of demonstrating that auditable measures of the present values of intangible assets cannot be made, all expenditures on such assets (i.e., intangibles) are recorded as expenses by accounting fiat.

*The Effect of the Biases on Measurements of Economic Performance.* The effect on recorded profit of not capitalizing intangibles depends on their past and current amounts and the rate at which they depreciate. Several economists have attempted to estimate the numbers, an exercise that requires some heroic assumptions. For example, Weiss (1969) assumed a constant annual growth rate of advertising and a constant rate at which past advertising expenditures depreciate. Robert Ayanian (1975), using those assumptions, showed that the rate at which advertising is assumed to depreciate is critical for calculating the economically correct rate of return. He estimated the depreciation rate by assuming a multivariable Cobb-Douglas production function for advertising. To estimate the parameters, ten years’ data were required. William Comanor and Thomas Wilson (1979) dismiss his results because they believe that advertising generally depreciates very rapidly. But the studies they cite are no better than Ayanian’s in measuring the depreciation rate because a basic characteristic of intangibles such as advertising is the difficulty, if not the impossibility, of estimating the value of expendi-

tures, future as well as current, even when one has complete knowledge about the company, its environment, and the specific projects and products to which the expenditures pertain. The issue is completely intractable when one must work with data aggregated into SIC-defined “industries.”

Given the caveats noted above, several effects of the divergence between accounting numbers and economic values on the profit rates on sales and assets ( $P/S$  and  $P/A$ ) can be specified. If the company is in a stable, zero growth state, such that the amount expended on intangibles exactly equals the depreciation of past, implicitly capitalized amounts,  $P/S$  is not affected but  $P/A$  is overstated, because past expenditures were not capitalized into assets. If the company’s expenditures on intangibles has been declining steadily and the depreciation rate of the intangibles is constant, profit is overstated because the decline in value of past written-off expenditures is greater than the amounts currently charged to expense; thus  $P/S$  is overstated. Since assets are understated as long as the past expenditures on intangibles have present value, the overstatement of  $P/A$  is even greater. When expenditures on intangibles are increasing and the depreciation rate is constant,  $P/S$  is understated. But, since assets also are understated, the effect on  $P/A$  is not determinable without additional information. Finally, when the growth rate of intangibles equals the real rate of return,  $P/A$  equals the real rate of return.<sup>15</sup>

The amount of intangible assets relative to tangible assets affects the magnitudes of these biases. Importantly, when the assumption of a constant rate of depreciation is false, neither the magnitudes nor the direction of the bias can be determined.

### (c) *Inventory Values and Cost of Goods Sold.*

*Accounting Procedures.* Accountants assign values to inventories according to several rigidly applied formulas that need not de-

<sup>15</sup>Ayanian’s discussion and illustrations show how difficult it is to make any a priori statements, even when constant rates of growth and decline of intangibles are assumed. Solomon also presents an excellent discussion.

pend on the physical movement of the goods. The first-in, first-out method (*FIFO*) assumes that the first goods purchased are the first sold or used in production; last-in, first-out (*LIFO*) makes the opposite assumption. An average of the prices paid is also an acceptable method. Or, when the items in inventory are relatively few and unique, the acquisition prices of the specific goods sold may be expensed as the cost of the goods sold. For all methods, the value of the goods in inventory should not exceed their market values, net of disposal cost. Thus, the amounts considered to be current expenses and the amounts treated as investments in assets (inventory), depends on the accounting method employed and the pattern of prices paid for the goods. None of the acceptable accounting methods records the cost of goods sold at their opportunity costs—the amounts foregone as a consequence of having sold the goods. In most (though not all) situations, this is the replacement cost of the goods. Nor, except possibly in supplementary schedules, are the goods in inventory valued at their market prices.

Several accounting procedures determine the amounts recorded for goods that a company manufactures. In addition to the conventions governing the cost of materials discussed above, some manufacturers use “standard-costing” to assign numbers to manufactured inventories. The standards applied differ among companies. Overhead, especially, is allocated to products according to several alternative criteria. These are usually arbitrary either because there is no conceptually meaningful way to assign costs that do not vary with output or are joint among outputs, or because the cost of determining the association between cost and output exceeds the benefits thereof. Furthermore, to the extent that overhead or direct costs include such accounting numbers as depreciation, the amounts charged to inventories and then to cost of goods sold diverge further from economic market values.

*The Effect of the Biases on Measurements of Economic Performance.* Short of a revaluation to opportunity costs of inventories and cost of goods sold, there is no way that the reported numbers can be adjusted to

economic market values. However, when the prices of materials and other costs of production are stable and equal to opportunity costs, the only important problems are the divergence of internal accounting numbers from economic market values (for example, depreciation) and the arbitrary allocation of overhead to specific goods and processes (unless a company produces only one good or product line in a plant).

When prices are changing, the method of assigning values to the goods sold and to those remaining in inventories becomes important. If prices are increasing steadily, the *LIFO* method will come the closest to recording costs of goods sold at economic market values. But the inventory will be understated. Hence, as long as the physical inventory does not decrease,  $P/S$  may be reasonably unbiased; but  $P/A$  is overstated. The *FIFO* method tends to value assets at current prices while profit is overstated. Thus both  $P/S$  and  $P/A$  are overstated. When prices are decreasing steadily, the reverse occurs—the overstatements are then understatements. However, since U.S. companies are legally required to use the same inventory costing method for tax returns as they do for their financial statements, they are likely to use *LIFO* in periods of steadily rising prices and then switch to *FIFO* if they believe that prices will steadily decline. (Taxpayers are permitted one unchallenged switch; they need not use the same costing method for all inventories.) But when price levels fluctuate, the direction of the bias is not unique. The effect of alternative overhead allocations to products is another indeterminate element. This is particularly troublesome for the FTC’s line of business data, since information on overhead allocations at the plant level is not reported.

(d) *Allocation of Joint and Common Costs and Assets to Lines of Business.*

*Accounting Procedures.* Many companies charge costs incurred above the plant level (company-wide costs) to current expense. Others allocate these costs to divisions or plants (rarely to products), using such bases as sales, direct labor cost, labor plus materials (prime) cost, and sales less variable costs

(contribution margin). When company-wide costs do not vary as a consequence of individual outputs or outputs aggregated by lines of business, any allocation method is arbitrary, and profit by product line cannot be determined. The amounts classified as company-wide rather than as plant-level also vary according to the accounting procedures adopted by individual companies. Such considerations as styles of management control, past accounting practices maintained for the sake of consistency, reduction of state taxes, and the degree of decentralized organization dictate the extent to which company-wide costs and assets are assigned to plants and divisions. In addition, the accounting numbers for company-wide assets and costs (such as depreciation of central facilities, general company advertising, and basic research and development) are unlikely to provide valid measures of the economic market costs attributable to products or product lines (as explained above).

*Effect of the Bias on Measures of Economic Performance.* The effect and direction of the divergence between the reported profit and asset amounts after or before allocations of company-wide costs and assets and the economically valid amounts is not determinable. Most enterprises are not merely mutual funds in which individual companies, each of which produces and sells a line of products specified by the FTC, are joined only by common ownership of a few resources general to all product lines. Rather, products usually are produced and/or sold together because they share joint demands, costs, or both. There is no conceptually valid way (with respect to economics) to allocate these joint revenues and costs to the individual lines of business. And, unless an analysis were made of how the common costs varied with individual products or product lines and could be avoided were production abandoned, there is no way of knowing how closely allocations made via some base, such as sales or direct expenses, approximate the correct amounts. Nor is there any way of knowing what portion of the company-wide costs and assets are joint or common, and how much the accounting numbers diverge from economic market values. Hence the effect of the bias of

allocating or not allocating those costs and assets designated as company-wide cannot be determined.

Nevertheless, economists at the FTC argue that, if reported company-wide costs were relatively small, they could be ignored. The FTC's *1974 Statistical Report* (1981a, pp. 62-70) states that 86 percent of the companies reported nontraceable costs.<sup>16</sup> Of these, 62 percent used a single base for making allocations (most used sales), 28 percent used two bases, and 10 percent used three bases. For the entire sample of company *LBs* (each of the FTC-defined lines of business of each reporting company) where a company has more than one line of business, the ratio of nontraceable to the sum of nontraceable and traceable amounts averages 14 percent for total selling and general and administration expenses and 12 percent for total assets. Nontraceable ratios over 20 percent are reported by 26 percent of the company *LBs* for expenses and 18 percent for assets. By *LB* industry aggregates, the weighted average nontraceable ratios are 15 percent for expenses and 13 percent for assets. Ratios over 20 percent are reported for 31 percent of the industries for expenses and 19 percent for assets. Thus, compared to the likely size of net profits, allocated expenses and assets are not negligible.

William Long (1981a) estimated some effects of allocating company-wide costs. (Alternative allocations of company-wide assets were not considered.) He did so by investigating the effect of alternative allocation methods on a regression of profit/sales on seventeen variables, using company *LB* data. Profit originally was calculated as gross profit (sales plus transfers less cost of sales) less direct and nontraceable expenses as allocated by the reporting companies.<sup>17</sup> When nontraceable selling and administrative expenses were reallocated according to sales or a sales-dominated base, the coefficients were not altered much, a result which is not

<sup>16</sup>The 1975 data are similar; see FTC (1981b, pp. 54-59).

<sup>17</sup>The original regression was run by David Ravenscraft (1982).

surprising since 69 percent of the companies allocating common costs used sales as their allocation base and most of the balance included sales in their bases. However, the effect of allocating these costs randomly (which, in the absence of theory or evidence on how the nontraceable expenses vary, has about as much validity as the other methods), Long reports, "is large and disastrous. The F-ratio plummets. Coefficients change signs. Significance levels are altered" (1981a, p. 21).<sup>18</sup>

Additional insights are obtained from an in-depth study of the financial data of six large companies by Robert Mautz and Fred Skousen (1968).<sup>19</sup> They recorded the net profit of company-determined business segments (three to nine segments for each company, thirty in all) as measured by each company's allocations of noninventoriable common expenses (excluding income taxes). Then they calculated the segment net profit after allocating the common expenses according to four additional, commonly used allocation bases (sales, total assets, number of employees, gross profits, and combinations thereof). The common expenses allocated are relatively less than in the FTC data set, averaging 3 percent of total expenses compared to 14 percent for the *LB* data,<sup>20</sup> probably because the company-determined segments tend to be broader than the SIC-

determined *LB*s. Consequently, Mautz and Skousen's allocations probably understate the magnitudes of the effects on net profit that might be found in the FTC data. Even then, the alternative allocation procedures yield very different rates of return (profit/assets). The differences can be summarized by dividing the range of the alternatively calculated returns by the company-determined return for each of the thirty business segments. (In percentages; a quotient of 0 means no difference among the alternatives.) The distribution of these percentage quotients is as follows:

0 to 5 percent—3 segments (10 percent);

6 to 10 percent—4 segments (13 percent);

11 to 20 percent—9 segments (30 percent);

21 to 40 percent—4 segments (13 percent);

41 to 60 percent—2 segments (7 percent);

61 to 80 percent—1 segment (3 percent);

141 to 843 percent—7 segments (23 percent).

With five observations deleted, four from the company with a very low percentage of common expenses and another with a very low company-determined profit rate, there are no observations in the 0–5 percent category, three instead of four in the 6–10 percent category, and six instead of seven in the over 141 percent category.<sup>21</sup>

Thus calculated product-line profit rates appear to be sensitive to the way indirect expenses are allocated, even when commonly used allocation methods are employed. Nor is there any *a priori* reason to favor one allocation method over another or even to know whether any of the methods yield economically meaningful numbers. Rather, the determinants of these expenses within each company should be analyzed empirically, a process that cannot be undertaken with the data requested by the FTC. Even then, where such expenses are jointly determined there is

<sup>18</sup>Long (1981a) also reallocated nontraceable advertising and other selling expenses and recalculated the equations he had calculated for another paper (1980). However, only an average of 3.6 percent of these costs are nontraceable and few (less than 10 percent) of the regression coefficients estimated are significant at the 5 percent level. Hence, though he found few significant changes in the coefficients and other statistics, the finding is not of much value for the present question. Stephen Martin (1981b) uses alternative definitions of total assets (for example, traceable and traceable plus nontraceable) as variables in regressions. Since he does not employ alternative allocation methods for nontraceable items, his results are not relevant here.

<sup>19</sup>Mautz and Skousen state that, although their sample was not randomly selected, "[t]ogether the six companies represent a broad cross-section of American Industry" (p. 19).

<sup>20</sup>One company had common expenses of only 0.5 percent of total expenses. With this company excluded, the average is 3.7 percent

<sup>21</sup>See my article for details (1979, Table 1–2).

no conceptual way to assign them to specific products or product lines.

(e) *Intrafirm Transfers Among Lines of Business.*

*Accounting Procedures.* Intrafirm transfers that are not priced at the opportunity value of the goods impart a mismeasurement of the sales of the sending business unit and the expenses of the receiving unit. For example, when transfers are priced at, say, cost rather than a greater market value, the sending unit's sales and the receiving unit's costs are understated. Because transfers at other than market prices could be repriced only at prohibitive expense, the FTC permitted respondents to report data as per their books, but also asked them to report the transfer pricing method. Transfers from one line of business to another are reported by 80 percent of the companies.<sup>22</sup> Of those transferring among lines of business, the transferred amounts (weighted by sales plus transfers, hereafter denoted as sales) average 8.9 percent of sales. Transfers above 9.9 percent of sales are reported for 24 percent of the company lines of business. Goods transferred to foreign activities (which are not included in the *LB* data) average 3.5 percent of sales (Ravenscraft, 1981, Table I). Thus transfers, while not great on average, are not negligible. Furthermore, differences in tax rates and bases among states and countries affect transfer pricing practices, which impart a systematic bias to the profits data.

The companies reported that they made 39 percent of their transfers at market prices. Cost plus markup was used in 26 percent of the transfers, cost was used for 13 percent, and "other" for 22 percent.<sup>23</sup> About half the

companies used more than one transfer pricing method.

*Effect of the Bias on Measures of Performance.* The size of the bias imparted by intrafirm transfers at other than market prices is analyzed by Ravenscraft (1981). For each company *LB* (3186 observations), he calculated the percentages to sales of transfers out and in that were priced at cost, cost plus markup, and other. These percentages were included as independent variables in regressions of *LB* profitability (profit/sales) on market structure and other variables. The coefficients of these variables show that, where transfers were at other than market, the profitability of the sending *LBs* is significantly lower and the profitability of the receiving *LBs* is significantly higher. Thus, the method of valuing transfers does matter. But he also finds that few of the coefficients of the other variables are affected; for all but two (rather unimportant) variables, the differences are negligible.

Ravenscraft also attempted to correct *LB* profits for transfers at nonmarket prices.<sup>24</sup> This adjustment was only partially successful; several of the measures of the transfers at nonmarket prices remained statistically significant in estimating profit/sales.<sup>25</sup> In comparison with Ravenscraft's original regression, the general conclusions were not altered appreciably, though several coefficients changed significantly.

Ravenscraft reports that the profit/sales measure (which the FTC claims would be useful to analysts) is changed as follows:

The average absolute change in operating income to sales for the 702 *LBs* is .0259, with a maximum change of .2540. In percentage terms, the average change in operating income to sales is 445%, with a maximum change of 17,595%.

<sup>22</sup> FTC (1981a, pp. 46-53). The 1974 data are similar.

<sup>23</sup> Ravenscraft reports sales weighted averages of 50.7 percent (market), 25.2 percent (cost plus markup), 9.4 percent (cost), and 14.7 percent (other). He states that "By far the two most common classifications in 'other' are negotiated value and market, list, or wholesale price less discount" (1981, p. 26, fn. 2). These methods apparently were used in about a third of the "other" lines of business. Though these methods seem to be close to market values, his regressions indicate that, in relation to market price, transfers at "other" prices were lower than transfers at cost or cost plus markup.

<sup>24</sup> The revaluation factor was calculated by dividing those industry sales and transfers that were valued at market by the cost of goods sold plus general and administrative expenses and less the amounts transferred at other than market. By this method, the profits of 22 percent of the *LBs* were reallocated.

<sup>25</sup> Curiously, the coefficients of transfers made at cost and cost plus markup change from significantly negative to significantly positive.

TABLE 2—REPORTED PROFIT RATE ON SALES OR ASSET WHEN COSTS ARE UNDERSTATED OR OVERSTATED BY A PERCENTAGE ERROR<sup>a</sup>

Understatement (–) or Overstatement (+) of Costs	Actual Profit Rate on Sales or Assets				
	0.05	0.10	0.15	0.20	0.30
–0.30	0.34	0.37	0.41	0.44	0.51
–0.20	0.24	0.28	0.32	0.36	0.44
–0.10	0.15	0.19	0.24	0.28	0.39
–0.05	0.10	0.15	0.19	0.24	0.34
+0.05	0.00	0.06	0.10	0.16	0.27
+0.10	–0.05	0.01	0.07	0.12	0.23
+0.20	–0.14	–0.08	–0.04	0.04	0.16
+0.30	–0.24	–0.20	–0.11	–0.04	0.09

<sup>a</sup> Calculated with formula derived in fn. 18.

[This is an average of the fifteen largest changes—so the actual maximum is higher.] The correlations between the original and reallocated profits is .8936. [1981, p. 10]

On the industry level, the two measures of profitability are highly correlated at .99. The average absolute change in the ratios is .0033; the average absolute percentage change expressed as percentages of the ratios is 11.5. But among the 237 industries reported by the FTC, there are some dramatic changes. The 10 industries with the largest changes show an average absolute percentage change of 170 percent, with a maximum of 590 percent. Thus individual profitability numbers can be considerably affected by transfers at other than market prices.

#### (f) *The Cumulative Impact of Accounting Biases.*

The extent to which accounting numbers diverge from economic market values cannot be determined, either as to magnitude or sign, but the effect of specified percentage divergencies can be determined analytically.<sup>26</sup>

<sup>26</sup> The following symbols are defined for this analysis:  $S$  = sales,  $C$  = costs,  $P = S - C$  = net profits,  $ps = P/S$  = profit rate sales,  $e$  = error in costs due to arbitrary allocations, etc., as a percentage of costs,  $C$ ;  $ps'$  = reported profit rate on sales when costs are over- or understated by  $e$ , and  $ps' = (S - C - Ce)/S = ps - e + eps$ . Since net profits/assets ( $pa$ ) is equal to net profits/sales ( $ps$ ) times sales over assets and neither sales nor assets are assumed to be affected by errors in costs, the effect on  $pa$  is the same as the effect on  $ps$ .

Table 2 shows the reported profit rate on sales or assets that results from a given percentage error in costs, compared to the "actual" profit rates. Divergencies due to nonmarket priced transfers and arbitrary allocations and mismeasurements of assets are ignored; Fisher and McGowan show that divergencies of accounting from economic depreciation alone is sufficient to make the accounting rate of return diverge significantly from the economic rate of return on assets. Even with these potentially important measurement errors implicitly assumed to be zero, the effect of an error in measured cost as small as  $\pm .10$  changes an actual profit rate of .15 to .07 or .24. A  $\pm .20$  error results in a stated profit rate of  $-.04$  or .32 rather than .15. Consequently, it seems evident that data measurement problems certainly might swamp inferences that otherwise might be drawn from the reported numbers.

2. *The Usefulness of Company Accounting Data.* From the analysis presented above, it might seem that accounting data are almost useless. In this event, one might ask, why do companies spend great sums to record, analyze, and report such data? The reason is that even if these data do not provide good measures of economic market values that are appropriate to other issues, they are useful to

The effect on the profit rate on sales or assets also can be expressed as an amount,  $x'$ , rather than as a percentage. In this event, the equation would be  $e(ps - 1) = x'$ .

company managers and outside observers of company activities for several very important purposes. These include internal control for managers and audits of company affairs for investors. These purposes do not require numbers that reflect economic values; rather numbers that reflect market transactions and responsibility for resources are required. When the reported figures are attested to by a certified public accountant, affirmation is made that an audit was conducted by an independent expert who verified the figures and tested the adequacy of the company's financial control system. The accounting numbers also can be evaluated in the context of the manager's or analyst's knowledge about the company's activities and past performance. Thus, the user of the numbers can formally or informally adjust them to account for idiosyncracies in the reported accounting procedures, their company-specific deviations from economic measures, and their relevance to particular questions being asked. (For example, what is the probability that the company can repay debt as promised?) Furthermore, changes in the reported numbers over time, within the context of the past and expected future economic conditions in which the company operates, may provide the user with useful information.

Accounting data also are used for decisions made within the firm, such as output and price decisions, and evaluations of product and managerial performance. For these purposes, the data rarely are used alone. Output and price decisions require estimates of opportunity costs, which often are available only from market data and special studies. Accounting measures of performance usually are evaluated within the context of the environment in which products are produced and managers operate. Thus the accounting numbers rarely are used alone or without specific knowledge of their limitations.

On the other hand, large-scale data bases, such as the FTC's *LB* program set, do not (and, probably even at very high cost, cannot) include much (if any) of the qualifying information available to company managers. When these data cannot be identified by firm

name (as is legally required for the FTC *LB* and Census programs), firm-specific information from other sources cannot be brought in. Thus the usefulness of the data for the FTC's announced purposes and for structure-performance studies generally is, at best, doubtful.

### C. *The Contamination and Completeness of LBs*

Companies normally do not record data according to the FTC-SIC-defined industries. To make the program feasible, the FTC permits the respondent companies to assign to a single *LB* all the data recorded for each "basic component".<sup>27</sup> Consequently, data properly belonging in one *LB* are reported in a different *LB*, resulting in under- and over-statements.

The FTC has sought to measure the extent by which reported sales data are contaminated and complete with a "specialization ratio" and a "coverage ratio." The specialization ratio is the ratio of the sales belonging in an *LB* category ("primary sales") to the sum of these sales and those included in this category but properly classified in another category ("secondary sales"). These ratios averaged .97 (weighted by total revenues) for the 1975 data; none is permitted to be below .85.<sup>28</sup> Thus, *revenue* contamination does not appear to be serious, except for relatively few industries. The coverage ratio is calculated as the ratio of primary sales reported in a category to the total sales of those products reported in all other categories. The weighted average over industries is .97 for the 1975 data. But 29 percent of the industries have percentages between .80 and .91, and 14 percent have

<sup>27</sup>A basic component is defined by the *LB* program as the organizational subunit which reports data. A corporate respondent typically has a number of components, and in many cases they cover products classified by the FTC in different *LBs*.

<sup>28</sup>If at least 85 percent of a component's sales is not accounted for by products classified in the same *LB*, the component must be further refined until the 85 percent rule is met. The ratios are described and the figures reported in FTC (1981b, pp. 41-46). The 1974 figures are similar.

percentages below .80. Thus, for a substantial number of industries, this measure shows a fairly high level of incompleteness in the sales reported.

Of much greater significance is the FTC's candid acknowledgement that "whether there is a significant relation between the degree of sales contamination for other variables [for example, expenses and assets] has not been established" (1981b, p. 43). Nor can it be established with the reported data, since the FTC's 85 percent specialization rules do not apply to expenses and assets, which need not and often do not vary directly with sales.<sup>29</sup> Hence, there is no way of knowing how serious the contamination is for such measures of performance as profit/sales and profit/assets.

Nor are these the only types of contamination. The FTC permits vertically integrated companies to combine data that other companies report as individual lines of business into a single *LB*. This contamination is permitted if more than 50 percent of an upstream (earlier processed) *LB*'s net operating revenues come from transfers to a downstream (later processed or sold) *LB*. A similar combination and contamination of data is permitted for backward transfers (for example, wholesaling combined with manufacturing). As a consequence of these permitted contaminations, additional overstatements and understatements of *LB* data will result.<sup>30</sup>

#### D. *The Stability and Reliability of the FTC's LB Data*

Although there is no way to determine how badly the FTC's *LB* data misrepresent economic market values or are contaminated among *LB*s with respect to expenses and assets, some insight into their validity may be provided by considering the temporal stability of the two key ratios—profit/assets and profit/sales. (Profit is defined as net operating income before interest and taxes.)

Academic researchers, industry analysts, and company managers are invited to use the ratios published in the FTC's *Statistical Reports* (1981a,b; 1982). The ratios reported are aggregates of company *LB*s. Thus differences among companies operating in the same FTC-defined industry are averaged. Nevertheless, the reported industry ratios vary considerably among the three (complete) years for which the data have been published—1974, 1975, and 1976. For example, for the ten median ranked industries in 1976, profit/assets for 1976 compared to 1975 changed by a mean absolute of 37.4 percent, and from 1974 to 1975 by 23.0 percent. The mean absolute change in profit/sales of these industries from 1975 to 1976 is 30.2 percent, and 23.3 percent from 1974 to 1975. The changes among years of the ten highest- and lowest-ranked industries are roughly similar. It is possible that changes in the environment in which the reporting companies operated or changes in the sample caused these differences. The errors of measurement described above also could be responsible for the differences between years.

The data reveal an even greater range with respect to the individual company *LB*s that are aggregated to obtain the industry averages and that are used as the dependent variables for several of the statistical studies discussed below. Excluded from these 1975 data are 889 company *LB*s that were not present in the previous year, had nonpositive assets, or were in SICs described as "miscellaneous" and "not classified elsewhere." Profit/sales (profit equals sales less traceable expenses) averages 7.9 percent (Stephen Martin, 1981a, Table 1, 1975 data, 2297 observations). The standard deviation is 14.1 percent, and the range is from less than -125.8 percent to over 58.9 percent (these are averages of the six lowest and highest percentages). Of these, 16.4 percent are negative and 3.0 percent indicate profitability rates of more than 30 percent.<sup>31</sup> Profit/traceable assets averages 23.6 percent (Martin,

<sup>29</sup>See Bock and my article (1975) for illustrations.

<sup>30</sup>For more on this issue see Bock and my article (1975).

<sup>31</sup>Profitability measured as sales less traceable and nontraceable expenses divided by sales shows a similarly wide range (Ravenscraft, 1982, Table A1).

1981b, Table II, PRA575, 1975 data, 2297 observations). The standard deviation is 170.0 percent and the range is from less than -227.8 percent to more than 2399.6 percent (averages of the six extreme values). Other definitions of assets show similarly wide variations.

If these data reflect the profit rates actually experienced by the reporting companies, it would imply very limited entry and exit into a substantial number of markets. Or, there could be substantial annual random variation in returns, which implies that the data measurement period should be longer than a year. Alternatively, the range of profit rates reported and the number of *LB*s with negative and very high positive profit rates could reflect the effects of accounting practices and allocations to FTC-defined industries. This effect would be exacerbated if the reporting company managers fear that their data will be used against them in anti-trust proceedings, despite the FTC's assurances to the contrary. If so, they can avoid reporting profits that antitrust enforcers might consider excessive or predatory in lines of business the authorities might consider to be suspect. Since the reported numbers must be reconciled with the company's total sales, expenses, and assets, the understatement of profits and profit rates in one *LB* results in an overstatement in the other *LB*s. As a consequence, the FTC anti-trust enforcers would be misled and the data would be subject to even more noise and biases.

### III. Analysis of Economic Studies Based on the FTC's *LB* Data

Though I believe that the biases and shortcomings of reported company accounting data and the FTC's *LB* data delineated above are overwhelming, there are those who strongly believe that these data are valuable if adjusted properly and used effectively. Therefore, the extent to which the reported studies prepared by the FTC's economics staff and consultants can fulfill the purposes specified by the agency are considered explicitly in this section. The working paper

status<sup>32</sup> of the studies reviewed should not shield them from public scrutiny, for several reasons. The *LB* program was proposed 14 years ago—in 1970. The costs of the program on the respondents has been considerable.<sup>33</sup> The nature of the data collected has been known since 1974. Hence, it is reasonable to expect the FTC's economists to have had well-structured hypotheses to which the data would be applied. Furthermore, it is useful to analyze working papers because they are more likely to present unsatisfactory and anomalous as well as satisfactory and expected findings than are published papers.<sup>34</sup> In addition, working papers often contain informative descriptions of the data that are not included in the shortened published revisions.<sup>35</sup> Finally, in this case, working papers can influence policy decisions.

The papers are grouped according to the four major study areas toward which the data appear to have been directed: economies of scale; structure-performance; research and development; and advertising and other selling expenses. All of the papers using *LB* data made available by the FTC through

<sup>32</sup>Several of them have been published, as noted in the references.

<sup>33</sup>See my article (1979, pp. 110–14) for an estimate of the prospective costs. Net of benefits (which were considered to be zero), the present value of the program's cost in 1974 dollars was calculated to be \$210 million, based on the FTC staff's estimate of \$24,000 per company. This estimate was vigorously disputed by the respondents as being greatly underestimated. See my article (1984) for an analysis of the FTC's and the respondents' calculations of the costs of the *LB* program, which concludes that the FTC staff grossly misestimated the costs.

<sup>34</sup>Unfortunately for the sake of knowledge, papers tend not to be published (or even submitted) unless they reveal statistically significant results that are in accord with accepted hypotheses. For example, Weiss reveals: "An empirical test by Hall and me [Marshall Hall and Weiss, 1967] apparently yielded a mild but significant positive relationship between firm size and profit rates among the few hundred largest industrial firms—a relationship which would have implied a capital-requirements barrier. I am more skeptical now because in subsequent unpublished work I have often found the relationship not to be significant" (1979, p. 1122).

<sup>35</sup>In particular, the published version of Martin (1983) does not include the ranges of the *LB* data, and the published version of Ravenscraft (1983) does not include information on the inter-range distribution.

the date when the *LB* program was to have been evaluated (March 1982) are considered so that readers would not think I had chosen only the poor papers.

#### A. *Economies of Scale*

Absent analysis of scale economies, there is no way of determining whether a measured positive relationship between profit and concentration was due to some sort of undesirable competitive behavior or to lower costs.<sup>36</sup> Obviously, the policy implications of these alternative explanations are diametrically opposed. Unfortunately, neither the paper reviewed next (the only one to address this question), nor any other study based on the *LB* data, can provide a meaningful measurement of economies of scale.

1. In "*Economies of Scale, Concentration, and Collusion*," Dennis Mueller (1980) states his objective as follows: "What we seek to explore in this [61 page] study, therefore, is the extent to which the efficiency-concentration-collusion interrelationships can be disentangled using data as disaggregated as the *LB* data are" (p. 5). Mueller attempted to estimate a Cobb-Douglas production function by regressing value-added (sales less materials) on payrolls, net plant and equipment/payrolls, and (in some equations) advertising/payrolls. He had to "assume that labor and capital stock are somehow pre-determined and exogenously given for any cross-section year" (p. 8). As an alternative measure of economies of scale, he regressed total cost on sales. The equations were run for each *LB* industry, the observations being company *LBs*, 1974 data. The estimated alternative measures of scale economies are weakly and negatively correlated, which is an indication that the models are poorly spec-

ified. But a much more important criticism is that neither of these forms could be meaningfully specified. The dependent variables, sales less materials and total costs, are determined by the interaction of supply and demand (and, importantly, by the companies' accounting systems). Therefore, even if the numbers used were meaningful measures of economic market values, there is no basis for determining whether the regressions trace out cost curves, demand curves, or the interaction of individual demand and cost curves. Thus there is no valid way to interpret the estimated coefficients.

Despite this crippling limitation, Mueller correlates the mislabeled "scale economies estimates" with several measures of concentration, stating: "If scale economies account for high concentration we expect a positive correlation between [the measures of scale economies and] the various concentration measures" (p. 25). Since the measures could reflect demand as well as supply conditions or simply bad data and poorly structured models, the small and generally negative correlations that he finds cannot be meaningfully interpreted.

In the penultimate section of his paper (ch. 4), Mueller attempts to distinguish collusion and economies of scale by assuming that all firms use the same technology, have the same cost function and the same products, and charge the same price. Given the broad FTC-SIC definitions of industries, these assumptions surely do not apply to the *LB* data set. Nevertheless, after some mathematical manipulations, he concludes: "Thus, while efficiency and collusion factors affect the pattern of costs and sales in a predictable way, their effects cannot be separated without imposing further restrictions and looking at more data than observations on firms within a single line of business" (p. 33). He then imposes several additional assumptions that, in effect, specify all firms in each *LB* industry as homogeneous with respect to economies of scale, degree of collusion, and elasticity of demand. After further manipulations and assumptions about the values of various parameters, Mueller concludes: "Attempts to estimate [the key equa-

<sup>36</sup>Even then economies of scope are ignored due to the separation of company data into FTC-designated lines of business. Furthermore, other efficiencies could be responsible for higher profit rates, as Peltzman suggests. Or efficiencies in the development and/or marketing of new products could be responsible, as Scherer (1979b) suggests.

tions] yielded disappointing results. Convergence was seldom achieved and even when achieved, the asymptotic standard errors often exceeded the regression coefficients. Moreover, whether or not congruence was achieved, the implications of the coefficients obtained were found to vary with the choice of deflator" (p. 47).

Thus the *LB* data are not even amenable to estimating what might be labeled (incorrectly) as economies of scale, without which the structure-performance studies cannot be used for policy purposes. Mueller's study is useful because it illustrates that the unreliability and inherent limitations of the *LB* data severely frustrate even a well-motivated investigator.

### B. Structure-Performance Studies

1. In "Structure-Profit Relationships at the Line of Business and Industry Levels," Ravenscraft (1982) inquires "whether profits rise with industry concentration when other structural variables, such as market share, are appropriately held constant. Also, what economic phenomena underlie the observed profit-market share associations?" (p. 17). Profit is defined as sales less direct (traceable) and allocated expenses divided by sales, as taken from the 1975 *LB* data for 3186 company *LB*s. Profit at the industry level is a similarly measured number derived from the 1975 *Annual Survey of Manufacturers* for 258 industries.<sup>37</sup> Those dependent variables are regressed on the fourteen variables listed in Table 3 plus nine additional variables for the company *LB* analysis. The industry regressions exclude the variables that relate only to company *LB*s.

Ravenscraft's study is seriously marred by the conceptual and empirical shortcomings of the dependent variable, profit/sales, which

also is used in several of the papers reviewed below as well as scores of others.<sup>38</sup> This ratio is justified as a proxy for the price-cost margin (price less marginal cost over price)—the Lerner Index. However, as Stanley Liebowitz (1984) shows, the Lerner Index is not a conceptually useful measure of monopoly or collusive pricing on which the antitrust authorities might base their actions (an emphasized goal of the FTC's *LB* program). At most, it only measures the marginal elasticity of demand; it does not measure the social cost of misallocated resources or even the amount of profits or wealth garnered from collusive pricing. Furthermore, differences in the price-cost margin among products or over time is a function of differences in marginal costs and exogenous shifts in demand.<sup>39</sup> Importantly for empirical work, as Stanley Ornstein (1975) demonstrates, the profit/sales ratio is not even a valid proxy for the Lerner Index. Recorded and allocated accounting expenses are not the same as economic costs on which the Lerner Index is based.<sup>40</sup> In addition, profit/

<sup>38</sup> Profits/assets is not used in any of the FTC-sponsored studies, except as follows. Ravenscraft states that: "With the ratio of operating income to *assets* as the dependent variable, only three conclusions change" (1982, p. 11, fn. 11). He does not otherwise mention this alternative dependent variable. Martin (1981b) regressed profits divided by six versions of assets as dependent variables. The coefficients of the independent variables differ considerably in significance and sometimes in sign from those of the same variables when profit/sales is the dependent variable. Furthermore, the coefficients differ considerably among the alternative measures of assets, often much more than can be accounted for by scale differences. For example, the Herfindahl index coefficient is statistically significant for only one version of the profits/assets, and three of the six coefficients of market size are significant.

<sup>39</sup> See Liebowitz (1984) for a thorough explication.

<sup>40</sup> Liebowitz (1982) shows empirically that the empirical price-cost margin is not a good proxy for either accounting profit over assets or equity, or a constructed measure of economic profits over sales (which ignores the accounting biases). Martin dismisses Liebowitz's work as follows:

Liebowitz (1982) criticizes the Census price-cost margin by comparison with Internal Revenue Service data. Scherer identifies two major problems with IRS data: the assignment of entire firms to a single industry (1980, p. 270) and the impact of accounting rules which are

<sup>37</sup> The regressions were replicated with 1974 and 1976 data. With a few exceptions, the coefficients are not significantly different among the samples, and almost all were statistically significant at the .10 level, in part because, as Ravenscraft states, "variables insignificant at the 10 percent level were eliminated by a stepwise procedure" (1982, p. 8).

sales differ among companies according to their degree of vertical integration and the extent to which they employ capital (since the factor price of capital is not included as an expense). Including assets/sales (or assets) as an independent variable to account for the bias is likely to lead to inefficient and biased estimators because the accounting number for assets usually is a very poor measure of the economic value of capital.<sup>41</sup> Indeed, in Ravenscraft's regressions (as in the other researchers' regressions), the coefficient of assets/sales is inexplicably significantly negative. It is likely that this coefficient, and probably others, is due to accounting-based biases.<sup>42</sup> Finally, the rela-

---

followed for tax purposes only (1980, p. 272). As noted above... Liebowitz corrects for the first problem (1982, pp. 238-39, footnote 22) [sic, fn. 21]. He recognizes the second (1982, p. 238, footnote 20), and assumes that it can be ignored. There is no reason to think this is the case, which invalidates his conclusion.

[1983, p. 32, fn. 20; emphasis added]

This criticism is curious, since it appears in a section of Martin's paper headed "The Lerner Index and Accounting Data," in which none of the measurement problems delineated in Section III above are mentioned. Furthermore, the accounting biases in the income tax data, about which Martin expresses concern, are no more serious than the biases in the FTC data that he uses, since the value weighting of the IRS sample overwhelms the additional biases imparted by small firms. Indeed, the IRS data are preferable, since they are not subject to the allocation biases inherent in the FTC *LB* data. (Also see Scherer, 1979b, pp. 200-05, for a demonstration of the biases introduced into industry numbers by the incorrect assumption of homogeneity.)

<sup>41</sup>For example, oil and gas producers severely under-value their major asset, oil and gas reserves, because they do not restate their assets at market values. Worse yet, large companies use successful efforts accounting, wherein only the exploration and development expenses of successful wells are capitalized. Their cost of sales, then, is understated if they use owned oil. But if they use imported oil (which, if purchased, is valued at market), these expenses are higher. If they are decreasing their exploration, drilling, and development activities, their expenses will be lower. Thus, how can the level of their profit rate on sales or, say, the coefficient of, assets/sales, be interpreted? Similar analyses could be made about any company or industry about which one is knowledgeable.

<sup>42</sup>An additional indication of such biases is given in Table 3, which compares the coefficients estimated by Ravenscraft with those estimated by Martin (1981a), who used similar data. (Note that most differences in scaling among the papers were adjusted for.)

tionship between profits/sales and concentration (or market share) should be specified as log linear if it is to serve as a proxy from profits/capital. Ornstein shows that, if this is not done (as it was not in the studies reviewed), statistically significant coefficients incorrectly result.

Aside from (or perhaps because of) the biased numbers used for the analysis, the meaning of the coefficients is difficult to assess. For the company *LB* regression, Ravenscraft finds that "Statistically, the most important variables are the positive effect of higher capacity utilization and industry growth, with the positive effect of market share running a close third" (1982, p. 11). Capacity utilization is measured as the smaller of "one" or the company's *LB* 1975 sales/1974 sales; industry growth is the ratio of the value of 1976 to 1972 shipments. Thus, the greater the increase in company *LB* sales or in industry shipments, the greater the increase in measured profit per dollar of sales. Does margin increase because expenses are less than proportionately variable? Or, were companies in expanding industries able to increase their selling prices more? Or, were industries with higher profit margins on sales able to grow faster?

Interpretation of reported market share is more important because this presumably bears on the profit-structure relationship in which Ravenscraft and others are interested. Ravenscraft expects a positive association of market share with profits for three reasons: "First, *LBs* with a large market share may have higher quality products or market power. Second, *LBs* with larger shares may be more efficient because of scale economies or because efficient *LBs* tend to grow more rapidly. Third, *LBs* with large market shares may be more innovative, or better able to develop innovations" (1982, pp. 2-3). Clearly, these alternative explanations not only have diametrically opposed policy implications (higher market power vs. other explanations), but they cannot be disentangled. In addition, if firms with larger market shares also have been in business longer and have relatively greater investments in fixed assets over an inflationary period, they will have lower depreciation expenses and possibly

TABLE 3—COMPARISON OF COEFFICIENTS ESTIMATED IN FOUR STUDIES USING FTC'S *LB* DATA<sup>a</sup>

Variables	1974 Data		1975 Data	
	Ravenscraft	Martin	Weiss-Pascoe	Scott

Notes: Ravenscraft (1982, Table I, 3186 observations); Martin (1981a, Table 15, corrected for heteroscedasticity, 2297 observations); Weiss and Pascoe (1981, Table 1, equation (4), 3043 observations, scale not given); Scott (1981, Table 7, equation 7-2, 480 observations, scale not given).

<sup>a</sup>Absolute *t*-statistics are shown in parentheses.

<sup>b</sup>Rescaled to Martin's magnitudes.

lower labor and other expenses (as capital is substituted). Consequently, higher market shares will be associated with higher profits, *ceteris paribus*. Or, the reporting companies could have allocated relatively less in common costs to the areas where they have greater market shares. Or, possibly transfers to these units were made at less than market prices. Without more information, implica-

tions should not be drawn from the coefficients measured.

Ravenscraft attempts to analyze a presumed market share (*MS*) relationship to profit/sales by regressing profit/sales on *MS* and *MS* times the other *LB* variables. He finds a negative coefficient for advertising/sales, a positive coefficient for industry advertising/sales, and a positive co-

efficient for the product of advertising and *MS*. He estimated that the *LB* companies made 47 percent of the sales in their industries, on the average, and calculated that profit/sales begins to increase when *MS* rises above 4 percent (p. 17). Assuming that these numbers are valid economic measures, should they be interpreted as meaning that firms with more than trivial market shares charge higher prices, offer higher quality products, economize more on other selling expenses, have a greater investment in capital, or what? Interpretation of the other measured relationships are subject to similar uncertainties.

Thus, despite Ravenscraft's imaginative econometric work, little can be learned, with one exception. He finds that when the company *LB* data are aggregated into industries, the results are different. The coefficient of the four-firm concentration ratio changes from significantly negative to significantly positive (probably, he notes, because company *LB* market share is not included in the industry regression). Five of the coefficients of the fifteen other common variables change from significance to insignificance (three also change sign), and all but two of the balance increase in magnitude by from two to five times. It appears, therefore, that analyses using industry data may have produced misleading results. Or do the regressions using company *LB* data produce misleading results? Or are the companies' allocations to FTC-defined *LBs* causing the differences? Or are the changes in the coefficients caused by differences in the independent variables specified in the company *LB* and in the industry regressions? At the least, these alternatives should lead one to wonder about the usefulness of the output of such exercises for public policy or business decisions.

2. "Market, Firm, and Economic Performance" (Martin, 1981a; 1983). Martin attempts to analyze the determinants of the price-cost margins of company *LBs*, where the profits/sales dependent variable was measured as reported sales (including transfers) less traceable expenses only divided by sales. Martin (1981a) specified thirty-two independent variables. Though he considers seventeen of these variables to be

endogenous, he estimated simultaneous equations only for the *LB* market share, firm market share, and *LB* selling efforts variables. The two-stage least squares estimates were corrected for heteroscedasticity; the corrected and uncorrected coefficients are presented. The observations are 2297 company *LBs* for 1975. Excluded are *LBs* that were not surveyed in 1974, and observations with nonpositive values for assets (since assets were converted to logarithms).

In Martin's profit/sales regression (1983), twenty of the twenty-seven coefficients reported are statistically significant at the .05 level or better, and four were at the .10 level.<sup>43</sup> Among the findings that might be of interest to the regulatory authorities, Martin finds a statistically significant (.01 level) positive coefficient for *LB* market share and a statistically significant negative coefficient for the Herfindahl concentration index. He concludes that "the market share coefficient may reflect either market power at the *LB* level, or the realization of scale economies, or both" (p. 48). Thus, without further information (which is not obtainable from the *LB* data), this finding is of little public policy value.<sup>44</sup>

Assets/sales, which was supposed to account for the unrecorded cost of capital em-

<sup>43</sup>He does not state (as does Ravenscraft) whether variables were eliminated with a stepwise procedure.

<sup>44</sup>In his earlier paper, Martin (1981a) attributed the unexpected negative coefficient of the Herfindahl index to a variety of possibilities (for example, suboptimal or excess capacity, X-inefficient, inflation, restrictions on exit following restrictions on entry, and market power expressed as reduced risk). He also recognized that the profitability measure (the dependent variable) does not reflect profit, but the profit rate on sales; hence, he acknowledges, the negative sign "may reflect a more than proportionate impact of market power on sales as compared to profit" (p. 33). However, in the published version, Martin states: "Although a number of ad hoc explanations could be offered for this result, I will not do so" (1983, p. 40). But in his conclusion he states: "The most likely explanation for this result is that oligopolistic coordination is less effective in recession years, while the very barriers to entry which engender market concentration impede exit in the short run" (p. 48). In neither the FTC nor the published version did he consider the possibility that the significant negative coefficient also might indicate misspecification of the model or data that do not reflect economic market values and impart biases.

ployed, has a negative, statistically significant (at the .01 level, with the second highest asymptotic *t*-statistic) coefficient.<sup>45</sup> This unexpected result is consistent with the "bad data" hypothesis, since the sign of this variable should be positive.

Two additional facts support the inappropriate model or bad data hypotheses. One is the values of the dependent variable, sales less traceable expenses/sales, which range from at least -125.8 percent to more than 58.9 percent (each are averages of six extreme values). Negative returns are present in 16.5 percent of Martin's observations (1981a; these data are not reported in the 1983 monograph). (Recall that 889 observations were screened out because they were new or labeled as miscellaneous.) As noted above, it seems very doubtful that these numbers could represent meaningful equilibrium economic profit rates. Second, as shown in Table 3, many of the coefficients (adjusted for differences in scaling) and *t*-statistics reported by Martin differ considerably from those reported by Ravenscraft (1982), even though they based their analyses on subsets of the same 1975 *LB* data. (Their dependent variables are somewhat different, since Ravenscraft deducted allocated expenses from sales while Martin did not; but they used thirteen independent variables that are almost identical.) These differences make descriptive statements about the profit-structure relationship of doubtful validity.

The possibility that biases in the data might have been responsible for his results is not recognized by Martin. In his published version (1983; a monograph, not constrained by extreme concerns for space), he hardly mentions biases in the data. Though he has a section partially labeled "accounting data," this contains only a conceptual criticism of Fisher and McGowan and some sentences stating that though "accounting measures...are likely to be...poor measures of the economic value of the capital stock [,]

...[t]his point is well known. ...[T]his measurement error is a serious problem only if it is systematically related to market structure. It is not obvious that this is the case" (p. 32). But, as is noted above in the discussion of Ravenscraft's paper (1982), such systematic biases could be present.

Furthermore, many of Martin's other findings can be attributed to biases in the data. For example, he reports that "non-advertising sales efforts at the firm level significantly increase *LB* profitability. A firm-level corporate marketing program is apparently a valuable asset, which increases profitability" (1983, p. 41). But, since Martin used *LB* profits before company-unallocated expenses, this finding also could simply reflect differences in accounting practices among companies, where those that allocate less (for example, centralized firms) have, as a consequence, higher measured *LB* profit rates and higher selling expenses at the firm level, *ceteris paribus*. Martin also concludes that "*LBs* which invest heavily in *R&D* are less profitable than other *LBs*, all else equal. This suggests that heavy *R&D* expenditures serve as an index of the intensity of conventional price competition, which apparently serves as a spur for research and development" (p. 42). But, since current *R&D* expenditures are called expenses, the finding might simply reflect accounting practice, and little else. On the other hand, firms that successfully invested in *R&D* in the past do not record the depreciation of this investment; hence their recorded profits are higher, *ceteris paribus*. Just how this might be related to market shares is not clear. In addition, Martin concludes that "a large firm-level *R&D* program enhances *LB* profitability" (1983, p. 46). But again this simply could reflect the interaction of Martin's measure of profitability and accounting allocation practices. Were there sufficient space, similar explanations of many of Martin's other findings could be provided.

3. "Some Early Results on the Concentration-Profits Relationship from the FTC's Line of Business Data" (Weiss and George Pascoe, 1981). The authors want to test Demsetz's (1974) hypothesis that concentration-related economies of scale (efficiency),

<sup>45</sup> Martin (1981b) explored this result more fully by running regressions with six alternative definitions of assets. (Assets defined as all except inventories fit the data best.) The results were substantially unchanged.

superior products or management, or luck is responsible for the often reported positive relationship between concentration and profits. To this end, Weiss and Pascoe regressed profits/sales on the variables listed in Table 3 plus an adjusted four-firm concentration ratio (adjusted "to correct for non-competing sub-products, inter-industry competition, local or regional markets, and imports" p. 2), an interactive concentration ratio equal to the concentration ratio times a ratio of consumer demand to total demand, imports as a percentage of domestic output plus imports less exports, and *LB* market share. The regressions were run with over 3000 observations, each a company *LB*, with 1974 and 1975 data separately. The *LB*s that were new (not reported in 1974) and discontinued (not reported in 1975 or 1976) were excluded, as were extreme outliers. The reported  $R^2$ s range between .04 and .07. The coefficients of market share are statistically significant ( $t$ -statistics over 5.6) and positive. Those for concentration are insignificant, except for the 1975 data when market share is excluded. The coefficients of the interactive concentration ratio is significant and negative in 1974 and not significant (though negative) in 1975. Thus market share dominates which, Weiss-Pascoe state, "provides some support for the Demsetz-Manke hypothesis, but it is not as compelling as it might have been if the relationship of margin with concentration excluding market share had been stronger" (p. 8).<sup>46</sup>

But, as noted above, profit per dollar of sales of companies in different SIC-defined industries is not a relevant measure, particularly since the coefficient of assets/sales, which is included to correct for the exclusion of the factor cost of capital, is significantly ( $t$ -statistic over 5.6) negative. In an effort to explain this result, they regress assets/sales on the other independent variables. They

offer some speculations about the results, but state: "These are at most hypotheses to be tested on other data and, hopefully, with some theoretical basis" (p. 11). I suggest that the observed and unexplained relationship between profit/sales and assets/sales is a measure of the divergence between economic market values and the accounting numbers used.

4. In "*Multimarket Contact and Economic Performance*," John Scott (1981) is concerned with measuring whether the presence of the same firms in several markets is associated with higher profits and, if so, whether these higher profits result from coordinated behavior, lower costs, or both. To answer these questions, Scott constructed a "new method of assessing multimarket contact" (p. 3). For each of twenty-four lines of business (1974 data) he paired 492 "competing" firms (246 pairs), based on the unverified assumption that firms with sales assigned to the same FTC-defined line of business necessarily were competitors. Then he recorded the number of other lines of business each reported and the number they reported in common. This "frequency of contact" was compared to the number expected if common *LB*s were randomly determined. He finds "significant multimarket contact among sellers" (p. 8), as evidenced from a greater number of observed common *LB*s (37 percent of the pairs) than are expected by chance (.10 level). But considering that firms are more likely than not to produce related products, this result is not surprising nor particularly significant. Also, since fewer than the expected number of common *LB*s (.10 level) were found for 31 percent of the pairs, the distribution is strongly bimodal. This result seems more surprising.

The fifty-one pairs of firms that had more contacts than expected by random selection were subjected to further tests. Scott finds "significantly less advertising and *R&D* intensities [ratios to sales] for lines of business where significant contact occurred" (p. 13). Apparently, firms that operated in related *LB*s experienced economies for some reason. In another test, Scott regressed operating profit/sales on the variables listed in Table 3

<sup>46</sup>They also find that "distance shipped" (a measure of geographic market share) is statistically significant (and negative). This is curious since the variable is an SIC industry-wide index based on 1963 data, which should be only tenuously related to the 1974 and 1975 company *LB* dependent variables.

plus a measure of industry minimum efficient scale, a dummy variable for the probability of greater multimarket contact above the sample median, and a dummy variable for a four-firm concentration ratio above the sample median. The product of the dummy variables also was included as a variable to measure the interaction of higher contact and higher concentration. The 492 selected firms (246 pairs) are the observations. With respect to his hypothesis, Scott finds significantly (.10 level) greater profit/sales that is about 3 percent higher for the higher-contact/higher-concentration variable. But whether this is due to greater efficiencies, barriers to mobility, collusion, accounting and classification biases, a relationship between vertical integration and number of "contacts," or some other factor cannot be determined from the analysis. Furthermore, as Table 3 shows, there are considerable differences between several of the *t*-statistics and signs of the coefficients Scott estimates and those estimated by Weiss and Pascoe, which renders the findings suspect.<sup>47</sup>

### C. Research and Development

1. In "Using Linked Patent and R&D Data to Measure Inter-Industry Technology Flows," Scherer (1981a) describes the procedures used in gathering data on 15,062 patents issued to 443 large industrial companies during a ten-month period (June 1976 through March 1977) and in assigning each patent to one or more lines of business. The companies' 1974 R&D expenditures per the FTC's *LB* reports then were associated with the inventions. The paper is very clear and honest in describing the great difficulties that were experienced in making the required associations. Though he was most imaginative in attempting to solve the problems, Scherer's expression of them makes it clear that they were "solved" only by making some heroic assumptions that severely compromise the meaningfulness of the resulting numbers.

Aside from questions of the meaningfulness of the data, the essential question is why the analysis was undertaken in the first place. In his introduction, Scherer states: "The motivation for developing these new data was straight-forward. During the 1970s... productivity growth [declined]. ...Beginning in the late 1960s,...privately-financed real R&D [similarly declined]. ...The key questions remain, what quantitative links exist between R&D and productivity growth, and did the parameters of any such relationships shift between the 1960s and the 1970s?" (pp. 1-2). Even if there were no questions about the validity of the data or the presumed decline in productivity, the matrix associating the number of patents issued and expenditures on R&D by *LB* that is presented at the close of the paper cannot answer this question since the R&D expenditures are not related to changes in productivity. Indeed, at best, all that is learned is that expenditures on R&D were made in some FTC-defined industries and that these expenditures *may* have been related to the output of these industries and other industries.

2. "The Propensity to Patent," Scherer (1980) uses the data just described because "they are a rich source of quantitative and qualitative information on technological change" (p. 1), and, to a lesser degree, on monopoly power. To these ends, Scherer regressed the number of patents issued to a company *LB* from June 1976 through March 1977 on eight technology class dummy variables, five variables measuring the type and scope of use, two variables designed to correct for some *LB* data reporting characteristics, the percentage of federal funding to total R&D expenditures, and a variable described only as "compositions of matter." All of the variables are multiplied by R&D expenditures and a constant term was added. The regressions were run with 1819 observations.

How this specification and the reported findings speak to the questions that presumably motivated the study is not clear. If the question asked is whether greater expenditures on research and development are positively related to a greater number of patents issued, an answer would hardly require a

<sup>47</sup>Differences in the coefficients' magnitudes could be due to the scaling of the variables; the means are not reported.

rigorous empirical study. It seems obvious that if more is spent on research and development, more patents will be applied for and granted. Another unremarkable major finding is that there are differences among industry groups. None of the empirical data provide "information on technological change." Monopoly power is measured by the concentration ratio, which was used to test the hypothesis that firms in more concentrated industries use patents as a means of securing their positions. The statistically significant, negatively signed coefficient would seem to disprove this hypothesis. Or, a critic of business behavior could argue that more highly concentrated industries have erected such great barriers to entry that they need not engage in further patenting. But Scherer dismisses this finding as being due to the highly concentrated automobile industry, which, he says, has few inventions. Or, given the quality of the data, there could be other biases present, as noted above.

3. In "*Inter-Industry Technology Flows and Productivity Growth*," Scherer (1981b; 1982) says that he "exploits a new, uniquely rich data source to analyze the relationships between research and development (*R&D*) and productivity growth" (1982, p. 627). Using the FTC's 1974 *LB* data, he associated *R&D* expenditures (cleverly, but given the nature of the data, necessarily crudely) with originating and using industries. He then regressed two productivity measures on the 1974 *R&D* expenditures divided by value-added and aggregated into two-digit manufacturing groups.<sup>48</sup> The productivity dependent variables are "total factor productivity growth" (not otherwise described) and sales/labor expense, expressed as changes over 1948–66, 1964–69, or 1973–78. Other analyses present simple correlations of various measures of productivity growth with *R&D* by industry of origin and industry of use,

broken down into "well measured" and "poorly measured" industry aggregates.

Unfortunately, Scherer infers causation from the correlation of *R&D* expenditures and productivity without providing a supportive conceptual or empirical basis. For example, a company could have higher measured productivity growth in a period which yields higher present or expected taxable profits. As a consequence, it might expend more on *R&D* because this is a tax deductible expense. Thus, the higher productivity (and profits) could have "caused" the higher expenditures on *R&D*. Or the company's 1974 expenditures on *R&D* might have been financed from the fruits of past productivity, and directed towards reducing material and capital expenditures and developing new products, rather than towards further increasing labor productivity. In this event, past productivity would be associated with present *R&D* expenditures, but these *R&D* expenditures would not be associated with future measured productivity. Or the regression coefficients simply may reflect mismeasurements. (The productivity measures are very crude.) And the amount expended on *R&D* is unlikely to measure the change in the stock, except in a steady state, at best. In addition, the industry aggregates are rather crudely defined. Therefore the regressions cannot provide evidence on the relationship between productivity and *R&D*, or even on whether research productivity has declined over some time period. Nor is Scherer justified in concluding "that the social returns during the 1970s [on *R&D* investment] appear to have been quite high" (1982, p. 633), since this conclusion is drawn from the coefficients of the regression of the productivity measures on *R&D* expenditures. There is no way of knowing from these data whether there is a causal relationship or even what the social return might have been.

4. "*The Effects of Inter-Firm Cooperation and Economies of Scale on Product Improving Research and Development Expenditures*" (Long, 1981b) begins: "The purpose of this paper is to perform an empirical analysis of the determination of research and development-

<sup>48</sup> The model calls for percentage changes in the stock of *R&D*, capital/labor and materials/labor. The *R&D* expenditure was assumed to measure the first variable; the other two were omitted.

expenditures for the improvement of the quality of manufactured products in the American economy for 1974 and 1975" (p. 1). For this purpose, Long proposed a model of *R&D* behavior and ran several regressions with data from 205 FTC-defined industries from 1974 to 1975 individually. It is difficult to evaluate the findings of this work, since it is incomplete. One thing that was learned is that the relationship between reported *R&D* expenditures/sales and number of patents issued differs considerably among FTC industries and, remarkably, often is negative and differs in sign between years. It is not clear whether this is a function of some underlying structure or of the quality of the reported data. In any event, it seems clear that the stated purpose of the paper—"the determination of research and development expenditures for the improvement of the quality of manufactured products"—neither was nor, given the FTC *LB* data, could have been fulfilled.

#### D. Advertising and Other Selling Expenses

1. In "*The Size of Selling Costs*," Weiss, Martin, and Pascoe (1981) seek "to explain selling expenses in manufacturing industries" (p. 5). They regressed advertising/sales, other selling costs/sales, and total selling costs/sales (separately) on five independent variables. The observations are 260 FTC-defined industries (1975 data). The authors learn that all three measures of selling costs/sales are positive significant functions of consumer demand/total demand, the distance products are shipped, and profit/sales—results that are not surprising. But they also find that selling cost/sales declines for concentration ratios greater than .51 for advertising and .39 for other selling costs. The descriptive or public policy implications of this finding (assuming that it is valid) are unclear. Do companies in more concentrated *LB* industries incur less selling expense/sales because they have achieved efficiencies? Or do they compete less in terms of selling expenses? Or have they spent more on selling in the past and now need not maintain consumer acceptance, while companies in less

concentrated industries have yet to inform (or possibly influence) consumers? These and other plausible hypotheses cannot be distinguished with the FTC *LB* data.

2. In "*Advertising Intensity, Market Share, Concentration and Degree of Cooperation*," Long (1980) wants to "assess the role that advertising plays in several explicit models of industrial organization and to formulate procedures for testing hypotheses which that assessment generates" (p. 1). To this end he developed a model which led him to estimate the following equation for each of 32 consumer goods "industries":  $\text{advertising}_i / \text{sales}_i = B_0 + B_1 \text{ market share of } i\text{th firm}$ , where  $i, \dots, n = \text{firms in an industry}$ . The regressions were run with 1974 company *LB* data and replicated in Long (1981) with 1975 data. While the  $B_0$  estimated are quite stable and generally statistically significant, relatively few of the  $B_1$  are significant, and many are inconsistent in magnitudes and even signs between years. Long concludes: "The predicted relation between advertising intensity and market share shows up clearly in only 25% of the cases examined; ...some evidence concerning the presence and impact of cooperation was produced, but it is not clearly persuasive; ..." and "virtually no evidence concerning economies of scale in advertising can be gleaned from this study, given its assumptions" (1980, p. 28). Whether the model tested has been largely disproved, was inadequately specified, or was unsuccessful due to the poor quality of data used cannot be determined. I suggest that if one reads the SIC descriptions of the *LB* industries listed in Long's Appendix B,<sup>49</sup> considerable weight would be given to the last explanation.

<sup>49</sup>For example, the first five "industries" are the following: meat packing, sausages and other prepared meat products, including bacon, ham, canned meats, and smoked and fresh meats; dairy products excluding fluid milk, including butter, cheese, condensed and evaporated milk, and ice cream; canned specialties, including baby food, baked beans, ethnic foods, health foods, and soup; frozen specialties, including baked goods (except breads), dinners, pizza and waffles; canned, dried, dehydrated, and pickled fruits and vegetables, including preserves, jams, jellies, dehydrated soup mixes, vegetable sauces and seasonings, and salad dressings.

#### IV. Summary and Conclusions

Several factors make aggregates of company accounting-determined data, such as those gathered by the FTC's Line of Business Program, of doubtful value for the purposes of economic analysis. Most important, perhaps, is the fact that the numbers reported, which are derived from the companies' accounting systems, do not reflect economic market values well. The biases caused by the divergencies of accounting numbers from economic values not only are likely to be considerable, but also impart biases to most of the reported numbers, particularly profits and assets. There is reason to expect the errors not to be randomly distributed and to yield measured, though invalid, relationships among the variables that purport to reflect the economic performance of companies in markets.

An additional important error follows from the FTC's use of the SIC categories and from the procedures companies must or can follow in reporting their data. The SIC-designated "industries" yield aggregates that are unlikely to be comprised of products that are substitutes in demand. The FTC's aggregation rules and purposeful reporting by companies that fear the data might be used against them further bias the data, so that it is not clear how well the reported numbers relate even to the industry categories as described in the SIC manual. While the FTC staff made some tests of the extent to which the sales were misallocated, there is no way that they can determine the extent to which expenses and assets were misallocated.

A review of the reported underlying numbers reveals that the variance of such measures of profitability as profit/sales and profit/assets is great. A fairly high proportion of the numbers are negative and the profit rates measured for a number of lines of business is enormously high. It is possible that these data reveal the profit rates actually experienced by the reporting companies and that a year is too short a period for useful measurement. However, I suggest that these data reflect the accounting biases present in the numbers. In either event, it is doubtful whether analyses using these data would yield

valid findings.

The twelve studies done by the FTC staff and consulting economists confirm this conclusion. Even aside from the data problems, the potentially important study on economies of scale is fatally flawed in concept. Without knowledge of economies of scale, the profit-structure studies cannot distinguish the effects of efficiency from the effects of collusion on a measured positive relationship between profitability and market structure. But most of the studies use profit/sales as their measure of profitability. It is not clear at all why profit before interest and taxes per dollar of sales is a measure of "profitability" among companies with different accounting procedures that greatly affect the rates. Nor does this metric, even were the accounting biases somehow adjusted, provide a useful measure for public policy or private resource allocation decisions. But these studies do provide some indication of the mismeasurement of the numbers, in that assets/sales was found to be strongly negatively related to profit/sales, while the reverse should be the situation. The studies that relate current expenditures on research and development to patenting and productivity infer causal relationships when there is no reason to expect them from the nature of the data that are or could be used. The studies concerned with selling expenditures are useful only in providing some descriptive data. Considering the limitations of the relatively well done econometric studies that use the considerably improved FTC *LB* data, it seems likely that other studies using less detailed data and often less sophisticated statistical methods are likely to be worse.

A final question that should be confronted is whether meaningful empirical work on the relationship between structure and performance is feasible. The answer, I believe, is that such work is useful, but not in the way much of it has been conducted. Joe Bain's (1951) often cited paper has led many economists to undertake and publish a very large number of misleading studies. These papers present what purports to be evidence that concentrated markets are associated with abnormally high profits, when it is likely that the positive coefficients were simply the re-

sult of biases in the accounting data used. The consequence not only is a misunderstanding of the working of the U.S. economy, but a possibly misguided antitrust policy that prohibits most horizontal and many other mergers.

If strong and convincing work on the relationships among profits, company size, market share, degree of competition and the like is to be conducted, it must take cognizance of the biases inherent in accounting and other data. It is very doubtful, though, that the required adjustments to the data can be made, particularly when these are aggregated in ways that cannot take account of significant differences among supposedly homogeneous observations. Rather, detailed company and industry studies, which require knowledge of the specifics and dynamics of events and institutions more than of econometric techniques, are needed.<sup>50</sup> In any event, continued sophisticated misuse of biased and irrelevant data is not the answer.

<sup>50</sup> Scherer's (1979b) delineation of the reasons for increased concentration both illustrates the type of analysis I have in mind and further supports the conclusion that statistical studies which associate variables aggregated by FTC-SIC-defined industries are fraught with error and a considerable potential for misinterpretation.

# Do Large Deficits Produce High Interest Rates?

By PAUL EVANS\*

There has been much concern recently that large U.S. deficits have, or will soon, produce high interest rates, thus hindering capital formation and economic growth in the United States and the rest of the world. This view seems to be held not only by the popular press, but also by many respected economists (for example, Martin Feldstein, 1983).

In this paper, I survey U.S. history to determine whether this concern has merit. There are three periods during which the federal deficit has exceeded 10 percent of national income. In none of these periods did interest rates rise appreciably. Regression analysis applied to data from these three periods has not uncovered a positive association between deficits and interest rates. There also appears to be no evidence for a positive association between deficits and interest rates during the postwar period. I conclude from this survey that the concerns of the popular press and many economists may be misplaced.

## I. The Conventional Macroeconomic Paradigm

Perhaps the most widely used paradigm in macroeconomics is the *IS-LM* model. Its widespread use reflects not merely that it is analytically tractable, but also that many economists generally agree with its structural

assumptions and with its implications, one of which is that increased deficits raise interest rates. In this section, I briefly point out the implications of the *IS-LM* model. I then discuss some of the problems that arise in estimating how strong the relationship is between deficits and interest rates and in testing whether increased deficits do indeed raise interest rates.

Because the *IS-LM* model is so familiar, I need not derive its implications here. I simply assert that it implies a relationship between "the" nominal interest rate  $R$  and real government spending  $G$ , the real deficit  $D$ , the real money stock  $M/P$ , the expected inflation rate  $\Pi$ , an error term  $US$  that measures autonomous private spending, and an error term  $UM$  that measures the level of autonomous money demand. To keep the analysis simple, it is assumed that the relationship is linear and purely contemporaneous:

$$(1) \quad R = a_0 + a_1G + a_2D + a_3(M/P) + a_4\Pi + a_5US + a_6UM,$$

where the  $a$ 's are parameters. Of course, in an empirical analysis of real-world data, dynamics would be important so one would have to treat the  $a$ 's here and the  $b$ 's and  $c$ 's below as polynomials in the lag operator. Therefore, what I say below about the  $a$ 's,  $b$ 's, and  $c$ 's actually applies to the long-run multipliers of  $G$ ,  $D$ , and  $M/P$ .

According to the paradigm, at any given nominal interest rate, total spending increases (i.e., the *IS* curve shifts rightward) when government spending rises while the deficit is kept constant (i.e., government spending and taxes rise by the same amount); when the deficit rises while government spending remains constant (i.e., taxes fall); when the expected inflation rate rises (i.e., the real interest rate falls); or when autonomous spending rises. Therefore, since the

\*Department of Economics, University of Houston, Houston, TX, 77004. I am grateful to Moses Abramovitz, Armen Alchian, Bob Barro, Martin Bailey, Michael Boskin, Charles Calomiris, Alex Field, Milton Friedman, Bob Hall, Doug Joines, Bob Lucas, Tom Mayer, Ben McCallum, John Seater, two referees, and the participants in seminars at Claremont College, the Federal Reserve Bank of San Francisco, Stanford University, Boston College, Ohio State University, Michigan State University, University of California-Santa Cruz, Swarthmore College, University of California-Irvine, the Federal Reserve Bank of St. Louis, Washington University, University of Chicago, and Lehrman Institute.

*LM* curve is upward sloping,  $a_1, a_2, a_4$ , and  $a_5$  are positive. The parameter  $a_3$  is negative and the parameter  $a_6$  is positive because decreasing the real money stock or increasing the autonomous demand for money lowers the spending that can be financed at any given nominal interest rate (i.e., shifts the *LM* curve leftward), thereby driving up the nominal interest rate.

Because the expected inflation rate  $\Pi$  is unobservable but may be systematically related to other variables, one should eliminate it from equation (1). Suppose that it is related to government spending, the deficit and the real money stock by

$$(2) \quad \Pi = b_0 + b_1 G + b_2 D + b_3 (M/P) + U\Pi$$

where the  $b$ 's are parameters and  $U\Pi$  is  $\Pi$ 's unsystematic part. Substituting equation (2) into equation (1) then yields

$$(3) \quad R = c_0 + c_1 G + c_2 D + c_3 (M/P) + U,$$

where

$$(4) \quad c_0 = a_0 + a_4 b_0,$$

$$(5) \quad c_1 = a_1 + a_4 b_1,$$

$$(6) \quad c_2 = a_2 + a_4 b_2,$$

$$(7) \quad c_3 = a_3 + a_4 b_3,$$

$$(8) \quad U = a_4 U\Pi + a_5 US + a_6 UM,$$

$$a_4, a_5, a_6 > 0.$$

Suppose that one estimates equation (3) consistently, treating  $U$  as an unobservable and unsystematic error term. The estimates converge in probability to  $a_1 + a_4 b_1$ ,  $a_2 + a_4 b_2$ , and  $a_3 + a_4 b_3$ , rather than  $a_1$ ,  $a_2$ , and  $a_3$ . For many purposes, this causes no trouble. For example, if one wants to know what an increased deficit does to nominal interest rates,  $a_2 + a_4 b_2$  is the right answer. On the other hand, if one wants to know what a larger deficit does to real interest rates,  $a_2$  is the right answer. Nevertheless, if  $b_1$ ,  $b_2$ , and  $b_3$  are nonnegative, one's estimates of  $c_1$ ,  $c_2$ , and  $c_3$  provide upper bounds for  $a_1$ ,  $a_2$ , and

$a_3$ . Therefore, if  $a_1 > 0$  and  $a_2 > 0$ , one should find that  $c_1 > 0$  and  $c_2 > 0$ . It is natural to assume that the  $b$ 's are nonnegative because in the *IS-LM* model increasing  $G$ ,  $D$ , or  $M/P$  raises aggregate demand and hence future inflation if the price level evinces any stickiness. Moreover, increased  $G$  or  $D$  may force increased money growth in the future, thereby raising the inflation rate. In such circumstances, reasonable behavior in forming expectations rules out negative  $b$ 's.

Even if government spending, the deficit, and the nominal money stock are completely exogenous variables, the ordinary least squares estimates  $\hat{c}_1$ ,  $\hat{c}_2$ , and  $\hat{c}_3$ , may not be consistent. The reason is that the error terms  $U\Pi$ ,  $US$ , and  $UM$  may have nonnegligible contemporaneous effects on the price level. For example, increasing  $U\Pi$  or  $US$  raises aggregate demand, simultaneously raising the nominal interest rate and putting upward pressure on the price level. If the price level should actually rise before  $U\Pi$ 's or  $US$ 's influence on the nominal interest rate has dissipated,  $M/P$  falls endogenously, tending to bias  $\hat{c}_3$  downward asymptotically. In contrast, increasing  $UM$  raises the interest rate but lowers aggregate demand, putting downward pressure on the price level. Consequently,  $\hat{c}_3$  may in fact be biased upward.<sup>1</sup> This bias is more serious, the less sticky the price level.

Ordinary least squares estimates of  $c_1$ ,  $c_2$ , and  $c_3$  may also be inconsistent because government spending, the deficit, and the nominal money stock may be correlated with the error term  $U$ . To see how this can happen, consider first increasing  $U\Pi$  or  $US$ . The nominal interest rate and output rise simultaneously. The increased output reduces some components of government spending, increases tax revenue and thus shrinks the deficit. Furthermore, the monetary authorities may accommodate some of the increased money demand that the higher spending induces. As a result,  $R$  rises while  $G$  and  $D$  are falling and  $M$  is rising endogenously.

<sup>1</sup>For simplicity, I assume that  $G$ ,  $D$ , and  $M$  are orthogonal so that one can treat each coefficient's bias in isolation.

Therefore, variance in  $UII$  or  $US$  biases  $\hat{c}_1$  and  $\hat{c}_2$  downward while biasing  $\hat{c}_3$  upward. Next, consider increasing  $UM$ . As the nominal interest rate is rising, output falls, leading government spending and the deficit to rise. The monetary authorities probably accommodate some of the extra autonomous money demand; hence  $M/P$  rises. Consequently, variance in  $UM$  biases  $\hat{c}_1$ ,  $\hat{c}_2$ , and  $\hat{c}_3$  upward. All in all, the endogeneity of  $G$ ,  $D$ ,  $M$ , and  $P$  spells inconsistent least squares estimates of  $c_1$ ,  $c_2$ , and  $c_3$ . The inconsistencies can be serious and of either sign, depending on how important is each source of endogeneity.

One must somehow overcome the problem of inconsistency detailed above. In this paper, I have overcome it in three ways. First, in three of my four sample periods, exogenous influences dominate the sample variances of government spending, tax revenue, and the nominal money stock. Second, I have used monthly data wherever possible so that I can reasonably take the real money stock as exogenous if the nominal stock is. Third, if I cannot reasonably take government spending, tax revenues, and the nominal or real money stock as exogenous, I estimate using two-stage least squares.

## II. The U.S. Experience during the Civil War

The Civil War broke out in 1861 and ended in 1865. Federal spending rose from 1.6 percent of national income in the four fiscal years prior to the war to 15.5 percent in the fiscal years 1862–65.<sup>2</sup> Little of the federal war effort was financed by taxes. Consequently, the deficit, which had averaged 0.5 percent of national income in the four fiscal years prior to the war, jumped to 12.1 percent during the war.<sup>3</sup> About one-

quarter of the deficit was monetized in 1862 and 1864, and over one-half was monetized in 1863. By 1865, however, the Union had succeeded in reducing monetization to 10 percent even though the deficit was appreciably larger than it had been in the previous three fiscal years.

Anyone taking the conventional paradigm seriously would predict from the above facts that interest rates must have risen sharply during the Civil War, especially after monetization fell in fiscal year 1865. Monetization might have held interest rates down somewhat, especially in fiscal year 1863. Because, however, the price level rose a great deal during the war,<sup>4</sup> it is unlikely that interest rates were held down much.

Figure 1 shows that this prediction is wide of the mark. I have plotted the deficit as a percent of national income and two interest rates, measured in percentage points per annum. The deficit ratio ( $DR$ ) jumped sharply during the war. Neither the commercial paper rate ( $CPR$ ), nor the railroad bond rate ( $RRBR$ ), shows any obvious correlation with the deficit ratio.<sup>5</sup> Indeed, the railroad bond rate tended to fall during most of the war. The commercial paper rate jumped in November 1860 upon President Lincoln's election, but fell as soon as the public had satisfied its increased liquidity preference.<sup>6</sup> It

---

real capital loss that a rising price level imposes on the holders of federal debt, add the real capital gains that indexing bestows, and add any rise in the market value of the debt. I use the official measure because it tells essentially the same story as a corrected measure would.

The first two corrections swell the *ex post* Civil War deficits by an average of 1.0 percent of national income. The reason is that much of the interest-bearing federal debt was indexed to gold (Wesley Mitchell, 1903) and the greenback price of gold rose more than the price level did. Because, however, no one at the time could be certain that interest and principal would actually be paid in gold, this correction is probably too large for the *ex ante* deficit.

<sup>4</sup>The Hoover *CPI*, which had fallen 0.7 percent a year between 1858 and 1861, rose 6 percent in 1862, 16 percent in 1863, 22 percent in 1864, and 11 percent in 1865 (all being fiscal years).

<sup>5</sup>The same is true of the New England municipal bond rate, an alternative measure of the long-term interest rate.

<sup>6</sup>Fear of war is well known to raise the demand for money.

<sup>2</sup>The years referred to in the paper are all fiscal years that run from July 1 to June 30. A data appendix, available from the author upon request, describes the data cited here, provides their sources and lists them.

<sup>3</sup>Here and elsewhere in the text, I have used the official measure of the federal deficit. It is well known, however, that this measure is incomplete when the price level is changing, when the federal debt is indexed, or when its market value changes. To obtain the correct measure, one must subtract from the official measure the

FIGURE 1. U.S. EXPERIENCE DURING THE CIVIL WAR

also drifted upward as the end of the war approached, perhaps reflecting the liquidity demand of southerners in anticipation of a Union victory and Reconstruction. In any case, the movement of the commercial paper rate was not closely related to the deficit.

Although the large Civil War deficits were not associated with sharply higher interest rates, they may nevertheless have had some effect. To determine how the deficits affected interest rates, I used two-stage least squares to fit the following regressions to annual data spanning the fiscal-year period 1858-69:<sup>7</sup>

$$(9) \quad \hat{CPR}_t = 7.48 + .583GR_t - .440DR_t$$

(1.05) (.364)      (.245)

$$- .373MR_t$$

(.291)

$$S.E. = 1.02, D-W = 2.29;$$

$$(10) \quad \hat{RRBR}_t = 7.42 + .295GR_t - .242DR_t$$

(0.26) (.090)      (.061)

$$- .300MR_t$$

(.072)

$$S.E. = 0.25, D-W = 1.75;$$

$$(11) \quad \hat{NEBR}_t = 5.52 + .342GR_t - .262DR_t$$

(0.16) (.055)      (.037)

$$- .222MR_t$$

(.044)

$$S.E. = 0.15, D-W = 2.17;$$

<sup>7</sup>I treated  $MR$  as endogenous, using as its instrument the nominal stock of paper money deflated by the Consumer Price Index lagged one year and trend real national income. Ordinary least squares, however, yielded similar results.

where  $t$  is an index of time;  $CPR$ ,  $RRBR$ , and  $NEBR$  are, respectively, the commercial paper rate, railroad bond rate, and New England municipal bond rate;  $GR$  is the ratio of real federal spending to trend real national income;  $DR$  is the ratio of the real deficit to trend real national income;  $MR$  is the ratio of the real stock of paper money outstanding at the end of each fiscal year to trend real national income; and standard

errors are shown in parentheses below each estimated coefficient.<sup>8</sup>

If one can interpret equations (9)–(11) as estimates of equation (3), *GR* and *DR* should have positive coefficients.<sup>9</sup> The ratio *GR* does indeed have positive coefficients, and two of the three are statistically significant at any reasonable level. In contrast, *DR* has negative coefficients with *t*-statistics  $-1.79$ ,  $-3.98$ , and  $-7.07$ . Since these *t*-statistics are significant at the 10, 1, and .1 percent levels, they provide strong evidence against the conventional paradigm. They also show that large Civil War deficits did not produce high interest rates. If anything, interest rates would have been lower, had the Union levied lower taxes, yielding a larger deficit.

The evidence is clearly less sophisticated than one would like to use. In particular, the regressions are based on only twelve observations and fairly crude data. Nevertheless, the evidence is fairly strong because the enormous sample variance of the independent variables reduces the need for a large sample.

The conventional paradigm has apparently failed. One therefore needs an explanation of its failure in order either to justify its continued use or to provide an alternative to it. I can think of six potential explanations for why federal deficits did not raise interest rates during the Civil War. First, the inflation premia in the nominal interest rates *CPR*, *RRBR*, and *NEBR* may have fallen as the deficit ratio rose. In terms of the analysis of Section I,  $b_2$  may have been negative enough to make  $c_2$  negative. A larger deficit may have lowered inflation expectations because the public may have believed Congress and the Lincoln Administration when they promised to return to the gold standard at

the prewar parity. After the gold standard was abandoned in December 1861, each increase in the deficit and hence in the price level meant that the price level had to fall by more to reattain the prewar parity.

This explanation makes sense for long-term interest rates like the railroad and New England municipal bond rates, but makes much less sense for short-term interest rates like the commercial paper rate. Probably households did not think that deflation would commence, or even that inflation would slow down much while the war was still going on. More likely, they expected the inflation rate to remain fairly close to what it was at the time.<sup>10</sup> If so, real *ex ante* short-term interest rates can be adequately proxied by the *ex post* real yields. These yields should then be increasing functions of the deficit ratio.<sup>11</sup>

<sup>10</sup>Using yields on greenback and gold government bonds, Richard Roll (1972) has calculated a one-year-ahead expected growth rate of the greenback price of gold for each week between May 2, 1863, and December 12, 1864. His series implies that even in 1863, when no one could reasonably have thought that the Civil War would soon end, the public expected the price of gold to fall over the next year, often by appreciable amounts. Although the price of gold is not entirely representative of prices in general, this evidence does suggest that the public actually expected deflation and that the argument of the previous paragraph might hold even for short-term interest rates. Because Roll based his estimates on strong assumptions, however, the hypothesis here still seems like a reasonable one.

<sup>11</sup>Given the hypothesis that actual and expected inflation rates differed by an independently and identically distributed error term, the estimated coefficients on *GR*, *DR*, and *MR* converge in probability to  $a_1 - (1 - a_4)b_1$ ,  $a_2 - (1 - a_4)b_2$ , and  $a_3 - (1 - a_4)b_3$ . In the standard *IS-LM* model, the parameter  $a_4$  is approximately  $1/[(1 + \beta/\alpha)(1 - \tau)]$ , where  $\alpha$ ,  $\beta$ , and  $\tau$  are the slope of the *LM* curve, minus the slope of the *IS* curve and the effective marginal tax rate on nominal interest income, respectively. Since  $\tau$  was close to zero during the Civil War,  $a_4$  lies between 0 and 1. If  $b_2$  is negative as the previous paragraph has argued it might be, the coefficient on *DR* is an upper bound to  $a_2$ . In this case, rejecting the hypothesis that this coefficient is positive is equivalent to rejecting the hypothesis that  $a_2$  is. In the more likely case that  $b_2$  is positive, however, failure to reject the null hypothesis is not evidence against the hypothesis that  $a_2 > 0$ . In any case, a positive  $a_2$  implies either that  $c_2$  is positive or that the coefficient on *DR* in the regression for the real interest rate is positive. One can obtain similar restrictions on the estimated coefficients of *GR* and *MR*.

<sup>8</sup>Throughout the empirical analysis, I have measured interest rates and ratios in percentage points. For example, equation (11) implies that increasing government spending by 1 percent of national income raised the New England municipal bond rate by .342 percentage points.

<sup>9</sup>Actually, the equation has *GR*, *DR*, and *MR* in it, rather than *G*, *D*, and *M/P*. In choosing this functional form, I am imposing the restriction of homogeneity; i.e., that doubling *G*, *D*, *M/P*, and the scale of the U.S. economy does not affect the equilibrium nominal and real interest rates.

To test this hypothesis, I fitted the following equation:<sup>12</sup>

$$(12) \quad RC\hat{P}R_t = 19.22 + 4.62GR_t - 4.15DR_t - 3.80MR_t, \\ (4.32) \quad (1.50) \quad (1.01) \quad (1.20)$$

$$S.E. = 4.22, D-W = 2.81;$$

where  $RCPR$  is  $CPR$  less the rate of consumer price inflation. Note that the coefficients on  $GR$  and  $MR$  support the conventional paradigm but the coefficient on  $DR$  does not. Moreover,  $DR$ 's coefficient is statistically significant at the .01 level. These results are similar to those for the nominal interest rates.

Second, usury ceilings (typically 6 percent; see Sidney Homer, 1963) may have prevented private borrowers from competing with the federal government. Again, it is hard to take this argument seriously, given the many ways borrowers and lenders have always found to get around usury laws. In particular, selling securities at discount was legal.

Third, patriotism may have spurred households to save enough more to finance the deficits. In empirical economics, however, appealing to variables as difficult to measure as patriotism is the last refuge of a scoundrel. Nevertheless, in Section IV, I do try to test this hypothesis, using a proxy for patriotism. I find no evidence that patriotism spurs saving.

Fourth, capital inflows from abroad may have financed the deficit.<sup>13</sup> Capital inflows, however, never exceeded 10 percent of the deficit during the Civil War.

Fifth, wartime disruptions may have reduced the profitability of investment, thereby reducing aggregate demand and interest rates.<sup>14</sup> Stanley Engerman (1966) has shown

that these disruptions were important and that they may have depressed investment appreciably. These facts, however, explain why interest rates were not higher on average during the Civil War, but not why interest rates were negatively related to the deficits. Many of the disruptions began at the start of the war and remained more or less constant until sometime after the war was over. For example, textile manufacturers lost their southern markets when the war started and did not regain them until well after Reconstruction had begun. Since the effect of the disruptions on aggregate demand was probably not very correlated with the deficit, they provide an unsatisfactory explanation for  $DR$ 's negative coefficients.

Sixth, private saving may automatically rise to finance increased deficits when the government is perceived to service the debt with future taxes. I elaborate further on this explanation in Sections IV and VI.

I have estimated analogues to regressions (9)–(12) in which  $DR_t + MF_{t-1}(1/P_t - 1/P_{t-1}) + IBDEBT_{t-1}(PG_t/P_t - PG_{t-1}/P_{t-1})$  replaced  $DR_t$ , where  $MF$  is the stock of federal paper money at the end of the fiscal year;  $IBDEBT$  is the interest-bearing federal debt at the end of the fiscal year, all of which I assume was indexed to gold;  $P$  is the average Consumer Price Index in the fiscal year; and  $PG$  is the average greenback price of gold in the fiscal year. The terms added to  $DR$  seem to serve largely as measurement error, yielding coefficients that are smaller in magnitude and less significant than those reported for  $DR$  above but that have the same sign. Therefore, "correcting" the official measure of the deficit does not change the conclusions reached above. Nor are they changed by replacing  $GR$ ,  $DR$ , and  $MR$  with  $\ln G$ , the logarithm of real tax revenue and  $\ln(M/P)$ .

### III. The U.S. Experience during World War I

In April 1917, the United States entered World War I, which lasted until November 1918. Federal spending rose rapidly from an average of 1.8 percent of  $GNP$  in (fiscal years) 1913–16 and the first three quarters of 1917 to 9.0 percent in the last quarter of

<sup>12</sup> The Durbin-Watson statistic does not imply statistically significant serial correlation since there are only eight degrees of freedom.

<sup>13</sup> Milton Friedman has suggested this possibility to me.

<sup>14</sup> I owe this point to Alex Field.

1917, to 18.5 percent in 1918 and to 23.0 percent in 1919.

The federal government financed more of this war with taxes than it had the Civil War. Nevertheless, the deficit rose from an average of 0.0 percent of *GNP* in the four fiscal years prior to the war to 6.4 percent in 1917:4, 13.2 percent in 1918, and 16.6 percent in 1919.<sup>15</sup> The Federal Reserve monetized 26.2 percent of the deficit in 1917:4, but reduced that figure to 8.9 percent in 1918 and to only 4.7 percent in 1919. Thus, the deficit was much less monetized during World War I than during the Civil War.

According to the conventional paradigm, the large deficits of World War I should have driven interest rates up sharply, especially in 1918 and 1919 when there was little monetization. Figure 2 shows that this prediction is just as wide of the mark for World War I as it was for the Civil War. As in Figure 1, I have plotted the commercial paper rate, the railroad bond rate, and the deficit ratio, labeling them *CPR*, *RRBR*, and *DR*, respectively. It is hard to see any correlation between *DR* and either *CPR* or *RRBR*. The railroad bond rate was rather stable.<sup>16</sup> The commercial paper rate moved around somewhat, but these movements were largely unrelated to the deficit ratio. In particular, the bulge in 1913 reflected a panic nipped in the bud by the issue of Aldrich-Vreeland currency;<sup>17</sup> and the bulge in 1914 followed the outbreak of World War I in Europe.

To show more rigorously that large deficits did not produce high interest rates during World War I, I have fitted the commercial paper rate and the railroad bond rate to constant terms, time trends, six lagged values of the respective dependent variable, and the current and six lagged values of *GR*, the ratio of real federal spending to trend real

*GNP*; *DR*, the ratio of the real deficit to trend real *GNP*; and *MR*, the ratio of the real *M2* money stock to trend real *GNP*.<sup>18</sup> I applied ordinary least squares to monthly observations spanning the period January 1914 to December 1920. Tables 1 and 2 report these regressions.

Although the *F*-statistics in Table 1 do not reveal a statistically significant relationship between the commercial paper rate and the right-hand side variables, there is one nonetheless. The coefficients for *GR* and *DR* sum to .261 and -.320, and have *t*-statistics 2.14 and -2.25. These sums are thus statistically significant at the .05 level. The conventional paradigm is consistent with the observed positive sum for *GR*'s coefficients, but is inconsistent with the observed negative sum for *DR*'s coefficients.

The *F*-statistics for *GR* and *DR* in Table 2 imply highly significant relationships. Furthermore, the coefficients for *GR* and *DR* sum to .0582 and -.0684, and have *t*-statistics 2.29 and -2.32. Again, the sums are statistically significant, the positive sum for *GR* is consistent with the conventional paradigm, and the negative sum for *DR* is not.

Table 3 provides further evidence that the conventional paradigm fails. The table reports the regression that I have fitted to *RCPR*, the *ex post* real commercial paper rate.<sup>19</sup> I assume that the estimated coefficients in the table can tell one something

<sup>15</sup>Adjusting the fiscal year 1918 and 1919 figures for inflation as discussed in fn. 4 reduced them by about 1.3 percent of *GNP*.

<sup>16</sup>The period August 1914 to November 1914 might have seen some movement in this interest rate; one cannot know because the bond markets were officially closed.

<sup>17</sup>See Milton Friedman and Anna Schwartz (1963, p. 172).

<sup>18</sup>See the data appendix for the definitions of these variables. Note that these regressions are monthly analogues to those estimated for the Civil War. I have included the lagged variables in order to capture the lag structure that an *IS-LM* model more sophisticated than the one analyzed in Section I would imply. The lag length 6 seems to estimate the lag structures well. The results reported in the text are hardly changed, however, by using 3, 9, and 12 lags, or by using polynomial distributed lags. The results are also little changed if one instruments for *MR*, using *M2* deflated by the previous month's wholesale price index and trend real *GNP*.

<sup>19</sup>I have assumed that the Federal Reserve obtained its series on the 4-6-month commercial paper rate by averaging the rates on paper divided equally among the 4, 5, and 6-month maturities. I have therefore used the formula  $RCPR_t = CPR_t - (1200/3)[\ln(P_{t+6}/P_t)/6 + \ln(P_{t+5}/P_t)/5 + \ln(P_{t+4}/P_t)/4]$ , where *P* is the wholesale price index.

<sup>a</sup>I treated *YD*, *D*, and *Y-G* as endogenous and all other right-hand side variables as exogenous. In all regressions, I used as instruments the constant term, Robert Gordon's natural output series, its products with the growth rate of the nominal *M2* money stock and with the marginal tax rate on income, the size of the military, and real government purchases. When I included *GT* and/or *FDEBT*, I added them to the list of instruments.

useful about how the *ex ante* real commercial paper rate responded to the federal spending ratio, the deficit ratio and the money ratio. (Footnote 11 provides some justification for so assuming.) Given this assumption, one can infer that the real commercial paper rate rose with the federal spending ratio because *GR*'s coefficients are jointly significant, summing to a highly significant 3.03. Furthermore, *RCPR* fell with the deficit ratio because its coefficients are jointly significant and sum to  $-3.85$ , which is highly significant. Finally, *RCPR* fell with the money ratio since *MR*'s coefficients are jointly significant and sum to  $-.796$ , which is statistically significant at the .05 level. The first and third finding are consistent with the conventional paradigm, but the second is not.

The paradigm fails just as badly for regressions in which  $\ln G$ , the logarithm of real tax revenue and  $\ln(M/P)$  replaced *GR*, *DR*, and *MR* and in regressions in which I replaced *DR* with  $DR_t - FDEBT_{t-1}(1/P_{t-1} - 1/P_t)$ , where *FDEBT* is end-of-month gross federal debt and *P* is the wholesale price index. This measure of the deficit excludes the real capital losses that inflation imposed on the holders of federal debt.

For the Civil War, I could only speculate on why the conventional macroeconomic paradigm failed. For World War I, data are available for determining where that paradigm went wrong. According to the paradigm, increasing the deficit while keeping government spending constant raises disposable income, thereby stimulating consumption at any given nominal and real interest rates. The World War I deficits, however, did not stimulate consumption spending much if at all. Table 4 reports the evidence for this assertion.

I fitted the regressions in Table 4 to annual data that span the period 1901 to 1929, using two-stage least squares. Regression (4.1) is the simplest possible consumption expenditure function.<sup>20</sup> It relates real consumption expenditure to *YD*, current real disposable income; which I measure as *Y*, real net national product; minus *G*, real

<sup>20</sup>It would be better to fit a consumption function, but only data on consumption expenditure are readily available. Consumption expenditure includes spending on consumer durables and does not include the service flow from the current stock of consumer durables. See the data appendix (available upon request) for more information.

government purchases of all branches of government; plus  $D$ , the real deficit of all branches of government.<sup>21</sup> This simple and conventional consumption expenditure function implies that, *ceteris paribus*, each dollar of deficit raised consumption expenditure by nearly a dollar. Consequently, the deficits during World War I should have driven interest rates up considerably.

Regression (4.2) shows that the current deficit did not affect consumption expenditure just through its effect on current disposable income.<sup>22</sup> The deficit has a highly significant, negative coefficient. In addition, the Durbin-Watson statistic jumps to 2.02 from 0.94 for regression (4.1), thus suggesting that regression (4.1) was misspecified by omitting  $D$ . The negative coefficient implies that an increased deficit raised consumption expenditure by much less than the marginal propensity to purchase consumption goods from  $Y - G$ . Households must therefore have treated  $Y - G$ , social disposable income, differently from  $D$ , the government's contribution to private disposable income—raising consumption expenditure much more when the former increased a given amount than when the latter did. Regression (4.3) rewrites regression (4.2) in a way that makes this distinction clear. It shows that the marginal propensity to purchase consumption goods is .979 from social disposable income, but is only .242 from the deficit.

Equation (4.3) suggests that households may have tried to spend some of the World War I deficits. (The coefficient on  $D$  is statistically significant at the .05 level.) Doing so would have tended to raise interest rates. Why then did interest rates not rise with the federal deficit? One answer consistent with the facts is that households really do have a positive marginal propensity to spend deficits, but that the relatively high marginal corporate profits tax rates in 1917–19 depressed the demand for business investment

by more than the deficits raised the demand for consumption expenditure.<sup>23</sup>

Robert Barro has provided a different answer. According to Barro (1974), households understand that a current deficit entails additional future tax liabilities equal in present value to the current deficit. For this reason, they do not regard a deficit as contributing to their permanent private disposable incomes any more than it is a contribution to social disposable income. Consequently, households do not try to spend deficits. The variable  $D$  in regression (4.3) has a statistically significant coefficient because  $D$  is highly correlated with the transitory part of  $G$ .<sup>24</sup> It is optimal for households facing any given current social disposable income to consume more, the higher the transitory part of  $G$ .<sup>25</sup> Therefore, the consumption expenditure function should have a statistically insignificant coefficient on the deficit if one has also included a good proxy for transitory government purchases.

Regression (4.4) shows the result of adding  $GT$ , my measure of transitory government purchases, to regression (4.3). (See the data appendix to learn how I constructed it.) The estimated coefficient on  $D$  loses all statistical significance and indeed becomes negative. Dropping  $D$  yields regression (4.5). The estimated coefficient on  $GT$  is positive and statistically significant, thus supporting Barro's hypothesis. The coefficient implies that increasing government purchases by a dollar lowered consumption expenditure by 28.2 cents less when the increase was transitory than when it was permanent.

Barro's (1981) analysis also implies that the transitory part of federal spending should affect interest rates much more than the permanent part. I have tried to test this implica-

<sup>21</sup>I am here following the advice of Michael Boskin (1978) in using private disposable income rather than personal disposable income.

<sup>22</sup>Lagged variables contributed no statistically significant explanatory power to equations (4.2)–(4.8).

<sup>23</sup>The effective corporate profits tax rate averaged 0.3 percent between 1901 and 1916, 32.8 percent between 1917 and 1919, and 12.1 percent between 1920 and 1929. See John Seater (1982, p. 363).

<sup>24</sup>See Barro (1979) for a theoretical rationalization for this correlation as well as empirical evidence that it is strong.

<sup>25</sup>This proposition is simply a corollary of the permanent income hypothesis. See Barro (1981) for a discussion of it.

tion but have had little success. It has proven hard to construct good monthly proxies for the permanent and transitory parts of the federal spending ratio  $GR$ .<sup>26</sup>

Regressions (4.6) and (4.7) provide evidence that households do not spend more on consumption goods when  $FDEBT$ , the beginning-of-year real stock of federal debt, is larger. In both regressions,  $FDEBT$  enters with a negative coefficient, which is, however, not statistically significant at the .05 level.

In regression (4.5) the marginal propensity to purchase consumption goods from permanent social disposable income is .969, a figure that seems too high. Furthermore, the constant term is negative but not statistically significant at the .05 level. I have therefore reestimated (4.5) excluding the constant term.<sup>27</sup> Regression (4.8) is the result. The marginal propensity is now the more reasonable value .932, and the coefficient on  $GT$  remains positive and statistically significant at the .05 level on a one-tailed test.

Barro has provided a consistent explanation for why large deficits did not produce high interest rates during the Civil War and World War I. His explanation is also consistent with how consumption expenditures behaved over the sample period 1901–29. Nevertheless, before leaving this section, it is desirable to examine another potential explanation for the unusually low consumption

expenditures during World War I—the price controls then in effect.

According to Frank Taussig (1919), the federal government applied price controls almost exclusively to the goods it was procuring. It did not control the prices of most goods sold at retail. The price controls were therefore essentially hidden excise taxes imposed on the sellers of war matériel to finance hidden expenditures on the war matériel. Since retail prices cleared markets, households may have found goods expensive to buy but not subject to rationing. Therefore, saving probably rose little more than it would have risen without the price controls.

#### IV. The U.S. Experience during World War II

The United States entered World War II in December 1941, and the war lasted until August 1945. Federal spending, which had averaged 12.1 percent of  $GNP$  in 1939–41, rose to an average of 41.3 percent in 1942–45. From an average of 2.6 percent of  $GNP$  in 1939–41, the deficit jumped to an average of 22.7 percent in the next four years.<sup>28</sup> On average, only 11.2 percent of these deficits was monetized, somewhat more than during World War I but much less than during the Civil War.

Using the conventional paradigm, one would predict that interest rates must have risen sharply during World War II. In fact, no such thing happened as can be seen from Figure 3, where I have plotted the commercial paper rate, Moody's Aaa bond rate, and the deficit ratio, labeling them  $CPR$ ,  $AAA$ , and  $DR$ , respectively. It is impossible to see any relationship between  $DR$  and either  $CPR$  or  $AAA$  because the deficit soared during the war while each interest rate followed a path resembling the cardiogram of a rock.

It is not difficult to understand why interest rates were so stable. During the war the Federal Reserve pegged the interest rates on Treasury securities, and interest rates on other securities maintained approximately

<sup>26</sup>One of my referees thinks that  $DR$  may enter my interest rate regressions with negative coefficients because interest rates respond more to the transitory component of  $GR$  than to the permanent component and because these two components are positively correlated. The variable  $DR$  then receives a negative coefficient because it is strongly correlated with the transitory component and because  $GR$  moves more than its transitory component. I have not tested this hypothesis because the univariate methods that I have employed for constructing the permanent and transitory components assume that the two components are orthogonal. To test this hypothesis would require a multivariate model of permanent federal spending, a model that I think would be almost impossible to construct satisfactorily.

<sup>27</sup>Since  $GT$  has an unconditional mean of zero, my proxy for it has a zero sample mean. Homotheticity of household preferences between current and future consumption of nondurables and the service flow from durables would then imply a zero constant term.

<sup>28</sup>Adjusting the World War II figures for inflation as discussed in fn. 4 lowers them on average by about 2.5 percent of  $GNP$ .

FIGURE 3. U.S. EXPERIENCE DURING WORLD WAR II

constant differentials reflecting differences in default risk, tax treatment, etc. The rates pegged were low enough to create excess demand for goods. Rather than letting the price level rise, the federal government imposed price controls, rationing the available output among eager demanders. Since the government was first in line, it obtained what it sought while consumers and investors obtained whatever the government chose to let them have of what remained. Table 5 shows that the government chose to take about three-fifths from consumption expenditure and about two-fifths from investment expenditure.<sup>29</sup> The government achieved this result by raising the portion of *GNP* absorbed as taxes by 5.9 percentage points, by raising the effective marginal tax rate on corporate profits from an average of 42 percent in 1939–41 to an average of 71.5 per-

cent in 1942–45,<sup>30</sup> and most important by extensive rationing controls.

I cannot directly test whether the large World War II deficits would have produced high interest rates, had interest rates not been pegged and had prices not been controlled. This proposition must necessarily be tested indirectly. I have based my test on the theory outlined below, which shows that there should be a *ceteris paribus* positive association between the deficit and the real money stock if deficits raise desired expenditure and hence unconstrained equilibrium interest rates.

When the government represses inflation and therefore must ration goods, the demand for the real money stock depends not only on real income and the nominal interest rate but also on how restrictive the rationing constraints are. To see why, consider a money demand model of the Baumol-Tobin type. When rationing is in effect, the interest earned by the asset alternative to money does not entitle the recipient to buy anything unless he or she can also obtain ration tickets. If  $R$  is the interest rate on the alternative asset

<sup>29</sup>Robert Gordon (1969) has shown that the figures in Table 5 substantially overstate the effective share of government purchases and understate the effective share of gross total investment. The official measure of government purchases includes, and the official measure of gross total investment excludes, \$45 billion in capital goods that businesses probably knew they would get when the war ended.

<sup>30</sup>See Seater.

TABLE 5—DATA FOR WORLD WAR II<sup>a</sup>

Years	Total Government Purchases/ <i>GNP</i>	Consumption Expenditure/ <i>GNP</i>	Gross Total Investment/ <i>GNP</i>
1939–41	16.3	69.8	13.9
1942–45	42.3	53.8	3.9
Change	26.0	–16.0	–10.0

<sup>a</sup>Shown in percent.

and  $Z$  is the shadow cost of ration tickets, the effective yield on the alternative asset is only  $R/(1+Z)$ ; which is smaller, the more binding rationing constraints are. Economic agents balance off this effective yield on the alternative asset against the transaction costs of shifts between the alternative asset and money. If the transaction costs are largely nonpecuniary—taking the form of inconvenience or, for many currency holders, the risk of going to prison for dealing in the black market—a higher  $Z$  implies little if any increase in transaction costs. Given a lower effective yield on the alternative asset but essentially the same transaction costs, economic agents increase their holdings of money as  $Z$  rises. (See my 1982 paper for more discussion.) I therefore assume that the money demand function takes the form

$$(13) \quad M/P = L\left(\underset{+}{Y}, \underset{-}{R}, \underset{+}{Z}, \underset{+}{UM}\right),$$

where  $M$  is the money stock,  $Y$  is real income,  $R$  is the nominal interest rate,  $Z$  is the shadow price of ration tickets, and  $UM$  is an error term. The function  $L$  is increasing in  $Y$  and  $Z$  and decreasing in  $R$  as indicated by the signs below  $Y$ ,  $R$ , and  $Z$ .

I assume that desired expenditure is given by

$$(14) \quad E = E\left(\underset{-}{Z}, \underset{+}{Y}, \underset{-}{R}, \underset{+}{M/P}, \underset{+}{G}, \underset{+}{D}, \underset{+}{UE}\right),$$

where  $UE$  is an error term. According to equation (14), desired expenditure is decreasing in the shadow price of ration tickets and the nominal interest rate,<sup>31</sup> and is increasing

in income, the real money stock, government spending and the deficit. For  $Z=0$ , equation (14) takes exactly the form that the conventional paradigm assumes. In particular,  $\partial E/\partial D > 0$  because increasing  $D$  raises private disposable income and thus raising desired consumption expenditure and desired total expenditure.

The government issues just enough ration tickets to permit the entire output  $Y$  to be purchased. In equilibrium,  $Z$  assumes the value that equates desired expenditure to output:

$$(15) \quad E(Z, Y, R, M/P, G, D, UE) = Y.$$

Since there were no formal markets in ration tickets during World War II and thus no direct measure of  $Z$ , one cannot estimate equations (13) and (15) individually. I therefore eliminate  $Z$  between them, obtaining the estimable reduced form<sup>32</sup>

$$(16) \quad M/P = F\left(\underset{+}{Y}, \underset{-}{R}, \underset{+}{G}, \underset{+}{D}, \underset{+}{UM}, \underset{+}{UE}\right).$$

I have estimated equation (16), applying ordinary least squares to monthly data that span the period October 1942 to December 1947. In the former month, Congress granted the Roosevelt Administration full power to

<sup>31</sup>Since price controls fix the price level over time,  $R$  is within a constant of the real interest rate.

<sup>32</sup>I assume here that the condition for market stability  $(\partial L/\partial Z)(\partial E/\partial(M/P)) < -\partial E/\partial Z$  holds. I also assume that  $Y$  is predetermined vis-à-vis  $UM$  and  $UE$  for at least a month, the sampling frequency of regressions reported below. Note that pegging  $R$  requires the Federal Reserve always to accommodate  $UM$ , so this assumption is sensible for this error term. It is also sensible for  $UE$  if it takes a month or more for economic agents to alter production and factor supply decisions in response to autonomous changes in expenditures.

set prices; by the latter month, controls had lapsed for the most part, and prices had risen enough to be near equilibrium levels. I assume that  $\ln(M/P)$  is approximately linear in an error term, which is a composite of  $UM$  and  $UZ$ ; and in  $\ln Y$ ,  $R$ ,  $GR$ , and  $DR$ .<sup>33</sup> Pretesting revealed that differencing the reduced form apparently eliminated the serial correlation in the residuals. What I obtained appears below:

$$(17) \quad \Delta \ln(\hat{M}_t/P_t) = .00704 + .325\Delta \ln Y_t \\ (.00315) \quad (.191) \\ - .271\Delta CPR_t + .00355\Delta GR_t - .00246\Delta DR_t, \\ (.134) \quad (.00159) \quad (.00145)$$

$$R^2 = .213, S.E. = .0227, D-W = 1.87.$$

Equation (17) generally confirms the theoretical predictions. The coefficient on  $R$  is negative, the coefficient on  $GR$  is positive, and both are statistically significant at the .05 level. What does not confirm the theory is  $DR$ 's coefficient. Rather than being positive, it is negative though not significantly so at the .05 level. Apparently desired expenditure did not rise with the deficit; if anything, it fell. Therefore, the large deficits during World War II would probably not have produced high interest rates even if interest rates had not been pegged and prices had not been controlled.

The federal government conscripted soldiers during the Civil War, World War I, and World War II. A referee has suggested that conscription may have imposed liquidity constraints on households, reducing consumption expenditure by an empirically important amount. The estimated effects of the deficit ratio on interest rates and desired expenditure may simply reflect a positive correlation of the deficit with conscription.

<sup>33</sup>I used the following proxies for  $M$ ,  $P$ ,  $Y$ ,  $R$ ,  $GR$ , and  $DR$ : the  $M1$  money stock; the Consumer Price Index; personal income deflated by the  $CPI$  (similar results obtain for industrial production); the commercial paper rate; and nominal federal spending and the nominal deficit deflated by the  $CPI$  and trend real  $GNP$ . See the data appendix, which describes and lists the data and provides their sources.

For World War II, I can test this hypothesis since good monthly data are available on military "employment," much of which was drafted. I have fitted a regression of the form (17) adding as an explanatory variable  $MILR$ , the ratio of military employment to the noninstitutional population. The result is

$$(18) \quad \Delta \ln(\hat{M}_t/P_t) = .00738 + .320\Delta \ln Y_t \\ (.00315) \quad (.190) \\ - .269\Delta CPR_t + .00310\Delta GR_t \\ (.133) \quad (.00163) \\ - .00225\Delta DR_t + .00829\Delta MILR_t, \\ (.00145) \quad (.00692)$$

$$R^2 = .233, S.E. = .0227, D-W = 1.89.$$

The coefficient on the deficit ratio remains negative, and the estimated military ratio has the wrong sign to support the hypothesis. This regression is also evidence against the joint hypothesis that patriotism reduced desired consumption expenditures and that it is well proxied by the size of the military.

The conclusions drawn from equation (17) do not change if one uses the ratio of the change in the real market value of gross federal debt to trend real  $GNP$  in place of  $DR$ .<sup>34</sup>

## V. The Postwar Experience

Several researchers have attempted to find an association between nominal interest rates and the U.S. deficit using postwar data. Although a few like Martin Feldstein and Otto Eckstein (1970) have found a weak positive, but statistically significant, association, many others have found none at all.<sup>35</sup> For refer-

<sup>34</sup>Table 7 of W. Michael Cox and Eric Hirschhorn (1983) provides the market value of the gross federal debt over the period between January 1942 and December 1980. Note that the ideal measure of the deficit is just the change in the real market value of federal indebtedness. The "corrected" deficits calculated above are only approximations to this ideal. The data of Cox and Hirschhorn permit one to calculate the ideal without approximation.

<sup>35</sup>See Thomas Sargent (1973).

FIGURE 4. U.S. EXPERIENCE SINCE OCTOBER 1979

ences to this literature and the best article in my opinion on the subject, see Charles Plosser (1982).

Most of these studies have three important weaknesses. First, the Federal Reserve stabilized interest rates over most of the postwar period, perhaps hiding the true relationship. Second, prior to the 1980's, the deficit was rarely large and did not vary much. When it did vary, it generally did so because of the business cycle. Third, the endogeneity of federal spending, deficits, and the money stock has often been ignored or poorly handled.

In this section, I investigate the relationship between interest rates and deficits in the period between October 1979 and December 1983. During this period, the Federal Reserve largely freed interest rates to seek their own levels. Furthermore, deficits became unusually large (in part because of the Reagan Administration tax cut);<sup>36</sup> they varied considerably; and much of that variance reflected such exogenous events as the defense

buildup, three cuts in personal income tax rates, the acceleration of depreciation allowances, and a tax hike. Therefore, if large deficits do produce high interest rates and one is ever to show that they do, one should be able to do so with these data.

Figure 4 plots the deficit ratio, the three-month Treasury bill rate, Moody's Aaa bond rate, and the *ex post* real one-month Treasury bill rate over the sample period, labeling them *DR*, *TBR*, *AAA*, and *RTBR*.<sup>37</sup> There is no obvious positive association between *DR* and either *TBR*, *AAA*, or *RTBR*. If anything, the plot suggests a negative association, which may, however, be misleading since the deficit was a highly endogenous variable during this period, rising in recessions and falling in booms. For this reason, it is important to estimate the relationship between interest rates and deficits, taking proper account of the endogeneity of the deficit.

I have fitted the three-month Treasury bill rate, Moody's Aaa bond rate, and the real one-month Treasury bill rate to constant terms, time trends, and current and past

<sup>36</sup>Barro (1983), however, has adduced evidence that deficits have not been unusually large, given the large amount of slack in the economy and the size of the government.

<sup>37</sup>*RTBR* is the one-month Treasury bill rate minus the *CPI* inflation rate over the next month.

TABLE 6—REGRESSIONS FOR THE PERIOD SINCE OCTOBER 1979<sup>a</sup>

	(6.1)	(6.2)	(6.3)	(6.4)	(6.5)	(6.6)

<sup>a</sup>Standard errors are shown in parentheses.

federal spending ratios, deficit ratios, and money ratios, using monthly data that span the period October 1979 to December 1983. I have treated the current values of the ratios as endogenous, using two-stage least squares.<sup>38</sup> Table 6 reports some regressions

that I have fitted. Regressions (6.1)–(6.3) include two lags on each right-hand side variable. In none of these regressions do the current and lagged values of the deficit have positive coefficients statistically significant at any reasonable level. Rather, they generally have negative, albeit insignificant, ones. Dropping the least significant variables sequentially, I eventually obtained regressions (6.4)–(6.6), the best fitting regressions that

<sup>38</sup>As instruments, I used the ratio of real federal spending by the Defense Department to trend real *GNP*; the ratio of federal employment to the population; two dummy variables; the discount rate of the New York Federal Reserve Bank; and bank borrowing from the Federal Reserve deflated by the *CPI* lagged one month and trend real *GNP*. One dummy variable was 0 from October 1979 to September 1981, 5 from October 1981 to June 1982, 15 from July 1982 until June 1983, and 25 from July 1983 until December 1983. These figures are roughly the percentage amounts that the Economic Recovery Act cut personal income tax rates. The other dummy variable was 0 from October 1979 to December 1982 and 1 from January 1983 to December 1983, when the Tax Equity and Fiscal Responsibility Act and the Highway Revenue Act were in effect. The federal defense spending ratio, the federal employment ratio, the two dummy variables, and the discount rate qualify as

an exogenous variables. Furthermore, over the sample period, the operating procedures of the Federal Reserve make bank borrowing a good candidate for exogeneity. Lagged reserve requirements essentially predetermined total reserves. The Federal Reserve had to supply the predetermined quantity of total reserves but could, through its control over nonborrowed reserves, fix the amount that the banks had to borrow in order to satisfy their reserve requirements, thereby influencing their portfolio decisions and the demand deposits that they supplied. Because the current price level might be affected by current Federal Reserve policy, I have deflated by the previous month's *CPI*.

retain *GR*, *DR*, and *MR* in some form. Each regression keeps only the contemporaneous terms *GR* and *DR*. In regressions (6.4) and (6.5), *GR* has positive coefficients that are statistically significant at the .05 level. These positive coefficients are consistent with the conventional paradigm. In contrast, *DR*'s uniformly negative coefficients are inconsistent with the conventional paradigm, especially the significant coefficients in regressions (6.4) and (6.5). I conclude from these results, not that the large deficits in 1982 and 1983 lowered interest rates, but rather that there is no evidence that they produced the high interest rates that have prevailed since October 1979.

Why have interest rates responded so little to deficits in the postwar period? Several studies, the best of which in my opinion is Roger Kormendi (1983), suggest that changes in the deficit in the postwar period have been offset by essentially equal changes in private saving, thereby removing the need for interest rates to change. See Kormendi for references to this literature.

## VI. An Explanation

What needs to be explained is why, in over a century of U.S. history, large deficits have never been associated with high interest rates, why the large increase in the deficit during World War I was associated with a large almost equal increase in private saving, why private saving has moved in the postwar period to offset changes in the deficit, and why large deficits apparently did not produce high aggregate demand. The explanation that seems most consistent with these observations is Barro's.<sup>39</sup>

Barro has argued that it may be optimal for households to react to an increased deficit by increasing their saving by an equal amount. Consequently, neither aggregate demand nor interest rates may rise. Households

will so react if capital markets are perfect, if they understand the intertemporal budget constraints they face, and if they have operative altruistic intergenerational transfer motives. They will then know that the current deficit equals in present value the taxes to service the extra debt. An increase in the deficit will therefore entail an equal increase in saving, which will just suffice to pay the extra future taxes levied on present households and subsequent generations for whom they care.

Macroeconomists have hesitated to accept Barro's argument, in part because they have doubted that households can foresee the higher future taxes implied by a larger deficit, and in part because they have doubted that households have altruistic intergenerational transfer motives. The assumption of accurate foresight of future tax liabilities does indeed seem implausible. One should, however, judge the utility of an assumption primarily by its predictive and explanatory power and not by its realism. The phenomena detailed above are consistent with accurate foresight but not with the very limited foresight assumed in the conventional paradigm.

Unlike the assumption of accurate foresight, the assumption of altruistic intergenerational transfer motives may actually turn out to be realistic. Laurence Kotlikoff and Lawrence Summers (1981) have presented evidence that the bulk of U.S. saving takes the form of intergenerational transfers.<sup>40</sup> Furthermore, casual observation suggests that households spend a great deal on their children—incomprehensible behavior if households actually have the preferences assumed in many macro models. Ultimately, however, the proof of this assumption lies in its predictive and explanatory power.

I have found for all of my samples that increasing the deficit ratio while keeping the federal spending ratio constant (i.e., cutting current average and marginal tax rates) actu-

<sup>39</sup>This explanation antedates Barro. In fact, it is generally termed *Ricardian equivalence* because Ricardo advanced it in his "Funding System." See Piero Sraffa (1951). Martin Bailey (1971) has also advanced this explanation.

<sup>40</sup>Franco Modigliani (1983) has presented some evidence that the figures of Kotlikoff and Summers are inflated. In any case, intergenerational transfers are probably empirically important.

ally lowers interest rates, generally by a statistically significant amount. I have never emphasized this finding, being content to show how little evidence there is that increased deficits raise interest rates. If, however, one should decide to take this finding seriously, what explanation can one offer? One possibility is that the lower tax rates associated with a larger deficit raise the after-tax real return to saving, raising saving appreciably as Boskin has argued. Therefore, private saving rises not only by enough to pay all future tax liabilities à la Barro, but also by an additional amount, thereby lowering aggregate demand and hence interest rates.

### VII. Conclusions

Economists like to think of economics as a science. In a science, however, repeated contradictions of a paradigm lead to its abandonment if there is any sensible alternative. One paradigm in economics implies that large deficits produce high interest rates. This paradigm is not supported by the facts. In over a century of U.S. history, large deficits have never been associated with high interest rates. Even the postwar periods separately offer no support for a positive association between deficits and interest rates. Indeed, the evidence more strongly supports a negative association than a positive one. Therefore, it seems that economists should be looking for an alternative paradigm to replace their current one. The previous section suggested that this paradigm should contain elements of Barro's model and should allow saving to increase with its real after-tax return.

This paper should not be taken to support deficit spending. In my view, which is the same as Barro's (1979), the government ought to run whatever deficit or surplus is necessary to flatten the expected future time profiles of its marginal tax rates. Deficits reduce welfare if they lead to an expected upward trend in marginal tax rates. Conversely, surpluses reduce welfare if they lead to an expected downward trend. Therefore, concern about current deficits should focus on whether federal spending will eventually be

cut enough that current marginal tax rates will finance it, or whether marginal tax rates will have to rise. Concern should not focus on what deficits do to interest rates, capital accumulation, or economic growth, for there is precious little evidence that deficits affect these variables.

# Transaction Costs in the Theory of Unemployment

By PETER HOWITT\*

This paper addresses the problem of accounting theoretically for the persistence of large-scale unemployment. It briefly reviews some of the well-known shortcomings of the Keynesian account based upon sticky wages and prices and upon Robert Clower's (1965) concept of effective demand, arguing that these shortcomings can be seen as a failure explicitly to integrate transaction costs into the theory of unemployment. The main constructive contribution of the paper is an example of a simple macro model, along the lines of Robert Barro and Herschel Grossman (1971), in which transaction costs are made explicit. An essential part of this example is an externality of the sort suggested by Peter Diamond (1982). The example provides an account of persistent unemployment with many Keynesian features, yet without some of the Keynesian shortcomings. In particular it assumes perfect wage and price flexibility.

## I. The Keynesian Account

For future reference, I sketch the standard Keynesian account in terms of Figure 1, reproduced in essence from Barro and Grossman (p. 86). Both the output and labor market are in excess supply at a real wage equal to its general equilibrium value,  $w^*$ . The supply of labor equals its notional demand  $n^*$ . But the effective demand, as given by the schedule  $ABn'$ , is only  $n'$ , because collectively the firms find themselves unable to sell any more output than can be produced by this amount. Thus the amount  $n^* - n'$  of unemployment exists.

\*University of Western Ontario, London, Ontario N6A 5C2, Canada. This paper has benefited from the helpful comments and criticisms of Joel Fried, Tom Kompas, Richard Manning, John McMillan, Tom Rymes, Dan Usher, and John Vanderkamp; none of whom is responsible for any shortcomings.

FIGURE 1

Over time the money wage and the price level will fall in response to excess supplies. This will generally raise the aggregate demand for goods, shifting the vertical portion of the effective demand for labor schedule to the right, and thus increasing employment. Less than full employment will persist if the process of deflation is slow, or if the effect of deflation on aggregate demand is small (or in the wrong direction). Involuntary unemployment will also persist, with  $w$  exceeding the supply price of labor, unless wages fall more rapidly than prices, driving real wages down to the point where effective demand equals notional supply.

This account has many virtues. It is consistent with the widely observed lags in wages and prices behind the business cycle with the countercyclical pattern of layoffs, and with the absence of any pronounced cyclical pattern to real wages. The assumption of quantity rationing underlying Clower's distinction between notional and effective demands also makes the approach consistent with the apparently involuntary nature of large-scale

unemployment, and with the observation that the typical business firm would usually prefer to increase its sales at the current price.

There are, however, some well-known shortcomings. As Barro (1977) has pointed out, the account gives no clear explanation of why the mutually advantageous gains from trade implied by the fact that the supply price of labor at  $n'$  is less than its marginal product remain persistently unexploited. Defenders of the approach often take this failure as a logical consequence of wage-price stickiness. But Barro points out that such stickiness can be explained by theories which predict that all potential gains from trade will be exhausted. For example, implicit contracts might specify efficient quantities of goods and services to be traded, along with money payments that are set in fixed ratio to the corresponding quantities in order to satisfy an independent condition of optimal risk sharing.<sup>1</sup> Thus something in addition to price stickiness must be adduced in order to explain the market failure in Figure 1.

That additional something is usually presented by defenders of theories of non-clearing markets as being the limitations imposed by transaction costs upon people's ability to communicate offers to buy and sell.<sup>2</sup> The stickiness of prices in Keynesian economics results not from a full set of pre-arranged contractual agreements but from an institutional assumption that prices must be set and advertised by agents (often personified collectively by the "auctioneer") before there is time for everyone to agree upon what quantities to trade. These costs are what prevent the exhaustion of all gains from trade. But the main problem with this line of defense is that the transaction costs are

not integrated explicitly into the theory of unemployment. They do not appear in the decision problems faced by agents, except sometimes as part of an explanation of the demand for money.

The problem is manifested in a difficulty with the concept of effective demand. Specifically, why doesn't the firm in Figure 1 try to remove its sales constraint by undercutting its rivals' price? If it made the conjecture most compatible with the price-taking assumptions of the Barro-Grossman model, it would see itself as being able to supply anywhere up to the entire market demand at anything less than the going price. In this case there would be no reason why the demand for labor should not be determined by the notional schedule in Figure 1, because a rational firm would ignore any constraint that could be removed by a negligible price reduction.<sup>3</sup> The concept of effective demand for labor would be redundant and there would be no unemployment in Figure 1. This difficulty might be resolved by invoking any of a number of costs of price adjustment. But the costs are absent from the standard Keynesian account.<sup>4</sup>

The problem is also revealed by recalling that, even if we accept the effective demand schedule  $ABn'$  as defining the relevant demand for labor, unemployment can persist in Figure 1 only if the money wage rate falls slowly relative to the price level. According to the usual textbook interpretation of the tatonnement process, this means that people remain unemployed only because they are slow to offer their services at less than the going wage. Similarly, the "contract" inter-

<sup>3</sup>This problem was pointed out by Don Patinkin (1965, p. 323, fn. 9).

<sup>4</sup>See, however, the attempt by Katsuhito Iwai (1981) to develop a general theory of nonclearing markets upon a microfoundation that makes explicit the institutional restrictions according to which firms set their prices. See also Geoffrey Woglom's (1982) macro model, in which the failure of firms to engage in competitive price reductions whenever they face prices in excess of marginal cost is based upon Joseph Stiglitz's (1979) analysis of markets with costly communication. Woglom's analysis is similar to the conjectural equilibrium analysis of Frank Hahn (1978), which provides another possible approach to resolving this difficulty.

<sup>1</sup>The model of Costas Azariadis (1975) actually implies a fixed real wage rather than the (temporarily) fixed nominal wage of Keynesian theory. However, Bennett McCallum (1978) has pointed out that the important qualitative implications of a natural-rate model with rational expectations and the Lucas aggregate-supply schedule, from which presumably all Keynesian elements of market failure are absent, would go through unaffected even if nominal and prices were preset by contractual agreements.

<sup>2</sup>See, for example, Axel Leijonhufvud (1968), Arthur Okun (1981), and David Laidler (1982).

pretation of Stanley Fischer (1977) and others requires the assumption that unemployed workers do not attempt to underbid anyone working on an unexpired contract (see Fischer, p. 198, fn. 17). This is not a convincing description of "involuntary" unemployment. As Axel Leijonhufvud stressed in his well-known critique, Keynesian economics thus agrees with the pre-Keynesian diagnosis that people are unemployed only because they are asking too much. One might defend Keynesian economics from this critique by arguing that the slowness with which the unemployed offer their services at less than the going wage is a theoretical proxy for the time cost of communicating and forming new matches in the labor market. But again these costs are absent from the account.

## II. Transaction Costs and Thin Markets

The preceding discussion attributes many of the shortcomings of the Keynesian account to the absence of explicit transaction costs, broadly interpreted to include costs of communication. It is a commonplace that such costs are higher the thinner the market; that the per unit cost of transacting depends inversely upon the amount of activity in the market. This observation refers not to the well-known economies of scale from lumpy set-up costs (for example, William Baumol, 1952), but to an externality whereby one agent's trading costs are reduced by having agents on the other side of the market devote more resources to trading.

The observation usually refers to cross-market comparisons, as between over-the-counter and regularly listed stock transactions, but it could equally well apply to intertemporal comparisons within any given market. For example, a decrease in the demand for labor makes it harder to find a job as well as reducing the wage, because potential employers advertise less and become less willing to arrange interviews, read job applications, return calls, and so forth.<sup>5</sup> From the

potential employer's point of view, the labor market becomes less thin when the number of unemployed workers searching for jobs increases and the cost of finding suitable potential recruits thereby decreases. In markets for consumer durables, when demand falls many people stop reading advertisements, stop visiting sellers, and generally become more difficult for sellers to contact. The phenomenon is especially marked in the housing market, where a decrease in demand not only reduces the market price but also increases the expected waiting time required to sell at that price.

This externality works mainly through the cost of communication. The extra cost of dealing in a thin market is primarily that of identifying, contacting, and negotiating with a suitable trading partner. This suggests that the externality is particularly difficult to internalize. Such internalization would generally require some kind of collective agreement to coordinate the activities of potential traders on both sides of the market. But the agreements themselves would require communications whose costs are subject to the externality. Once two potential trading partners have contacted one another, it is generally too late for them to agree to an arrangement to share the costs of contacting in such a way as to induce the efficient amount of contacting activity by each side.<sup>6</sup>

Some internalization obviously is accomplished by intermediaries in the labor market, such as employment agencies, university placement services, newspapers, and trade associations; as well as by retail and wholesale firms, auction houses, jobbers, specialist traders, financial intermediaries, real estate agents, etc. in other markets. But the scope of such intermediation in labor markets is limited by the problems of heterogeneity and

<sup>5</sup>How this can happen and why searching workers are affected by this change in recruiting behavior independently of its effects on wages is described graphically by Okun's analysis of "No-Help-Wanted signs" (pp. 56-61).

<sup>6</sup>Such arrangements are analyzed by Dale Mortenson (1982). As he points out, they are most likely to occur in markets intermediated by brokers who have dealt with each other in the past, either directly or through their common membership in some organized institution, and have thus had the occasion to reach some understanding prior to their current contacting activities. The brokers also need to have an expectation that their mutual dealings will continue in the future in order to have an incentive to adhere *ex post* to agreements that do not have the force of law.

asymmetry of information, which tend to render large-scale intermediation uneconomical. Even in other markets there is no reason to think *a priori* that intermediation eliminates all substantial externalities.

An example of a formal model of this kind of externality was provided by Robert Jones (1976), who based his explanation of the emergence of monetary exchange upon a search model in which the expected time required to contact a trading partner depended inversely upon the number of such potential partners actively in the market.

Diamond has shown, using this kind of search model, how the externality can explain "low-level" equilibria in very special models, which are suggestive of fixed price excess-supply equilibria but without the fixed prices. In these models, a widespread expectation of high costs of contacting trading partners can be self-fulfilling. It will discourage production, thereby resulting in a low volume of trade, and thereby bringing about the expected high cost by thinning out markets.

### III. An Example

The example of this section can be seen as recasting into more familiar macroeconomic terms the basic results of Diamond.<sup>7</sup> Rather than focus exclusively upon one of the many informational, logistical, institutional or strategic factors underlying transaction costs I shall model such costs in the less explicit but more general manner of such writers as Frank Hahn (1971), and Jürg Niehans (1971).

<sup>7</sup>The differences between this model and Diamond's are that: (a) Diamond's model has essentially one kind of agent and one kind of good, rather than firms and households and labor and output; (b) his production technology is described by an exogenous Poisson process rather than a usual short-run production function; (c) his model has no congestion externalities; (d) he describes unemployment as waiting for a production opportunity and employment as searching for a trading partner, which on the face of it seems to get it the wrong way around, whereas this model has more conventional descriptions; (e) his model is explicitly dynamic whereas this one is static; and (f) his model is more explicit about the institutional arrangements underlying transaction costs.

Specifically, assume that traders are convened by an auctioneer (or a set of specialist auctioneers) able to find market-clearing wages and prices at no cost, but unable to arrange the trades costlessly. There are unspecified trading institutions in place that reduce but do not eliminate the trading costs faced by households and firms. In addition to the usual budget constraint, there is a transaction-cost constraint requiring each trader to use up resources in order to execute his planned transactions.

There are only two markets, labor and output; and two types of traders, identical households and identical firms. Let  $\bar{y}$ ,  $\bar{s}_y$ , and  $\bar{b}_y$  denote the quantity of output traded in the market, the amount of output used up by all firms in selling output (their "marketing effort"), and the amount of output used up by households in buying output (their "buying effort"), all measured as aggregate quantities per firm. Each firm takes these quantities as given and faces the transaction-cost constraints:

$$(1) \quad s_y = \bar{\sigma}(\bar{s}_y, \bar{b}_y) y,$$

where  $s_y$  is his own marketing effort,  $y$  is the quantity he plans to sell, and <sup>8</sup>

$$(2) \quad \bar{\sigma} > 0, \quad \bar{\sigma}_1 > 0, \quad \bar{\sigma}_2 < 0.$$

Equation (1) asserts that his selling cost must be incurred in the form of output used up, and that this cost is proportional to the volume of his transactions.<sup>9</sup> The negative dependency upon households' buying effort asserted in (2) represents the externality described in the previous section. The positive dependency upon the marketing effort of the firm's rivals represents an external diseconomy that might reasonably be supposed to

<sup>8</sup>All functions are assumed to be smooth. Partial derivatives are denoted by subscripts. Unless otherwise indicated the domain of each function introduced consists of all strictly positive values of its arguments, and unqualified statements like (2) are understood to hold over the entire domain of the functions involved. All prices and quantities are understood to be strictly positive unless otherwise indicated.

<sup>9</sup>This assumes away the important phenomenon of set-up costs.

counteract that external economy. For example, more advertising and product promotion by rivals might require the firm to increase its own efforts to avoid losing customers.<sup>10</sup>

Averaging (1) across all firms yields

$$(3) \quad \bar{s}_y = \bar{\sigma}(\bar{s}_y, \bar{b}_y) \bar{y}.$$

Assume that households' transaction-cost constraints require a buying effort proportional to the quantity bought. Thus  $\bar{b}_y = \beta_y \bar{y}$  for some constant  $\beta_y \in (0, 1)$ . By specifying  $\beta_y$  as a constant in this example, I am ignoring the external economy conferred upon buyers when firms spent more upon marketing. Substituting for  $\bar{b}_y$  in (3) produces the equation:

$$(4) \quad \bar{s}_y = \bar{\sigma}(\bar{s}_y, \beta_y \bar{y}) \cdot \bar{y}.$$

Assume that for any  $\bar{y} > 0$  there is some  $\bar{s}_y$  satisfying (4), and that

$$(5) \quad \bar{\sigma}_1(\bar{s}_y, \beta_y \bar{y}) \cdot \bar{y} < 1 \quad \text{for all } (\bar{s}_y, \bar{y}).$$

Inequality (5) asserts that a firm does not have to match an increase in its rivals' marketing effort in order to maintain constant sales. These two assumptions imply that (4) can be expressed as:  $\bar{s}_y = \bar{s}_y(\bar{y})$ , with

$$(6) \quad \bar{s}_y'(\bar{y}) = (\bar{\sigma} + \beta_y \bar{y} \bar{\sigma}_2) / (1 - \bar{\sigma}_1 \cdot \bar{y}).$$

Thus the per unit selling cost faced by each firm will be

$$(7) \quad \sigma(\bar{y}) \equiv \frac{\bar{s}_y(\bar{y})}{\bar{y}} \equiv \bar{\sigma}(\bar{s}_y(\bar{y}), \beta_y \bar{y}).$$

Assume that the external economy dominates the congestion externality, in the sense that a proportional increase in both marketing efforts and buying efforts will reduce the per unit selling cost:

$$(8) \quad d\bar{\sigma}(\theta s, \theta b)/d\theta < 0.$$

<sup>10</sup> Such diseconomies are made explicit in the context of hiring labor, rather than selling output, by the analysis of myself and Preston McAfee (1983).

Then an increase in the market quantity will cause a decrease in the per unit cost of selling:

$$(9) \quad \begin{aligned} \sigma'(\bar{y}) &= (1/\bar{y}) (\bar{s}_y'(\bar{y}) - \bar{s}_y(\bar{y})/\bar{y}) \\ &= (1/\bar{y}) (\bar{y} \bar{\sigma} \bar{\sigma}_1 + \bar{y} \beta_y \bar{\sigma}_2) / (1 - \bar{y} \bar{\sigma}_1) \\ &= (1/\bar{y}) (1/(1 - \bar{y} \bar{\sigma}_1)) \\ &\quad \cdot \frac{d}{d\theta} \bar{\sigma}(\theta \bar{s}_y(\bar{y}), \theta \beta_y \bar{y})|_{\theta=1} < 0, \end{aligned}$$

(from equations (5)–(8)).

Finally, assume that

$$(10) \quad 1 + \bar{\sigma} + \bar{y}(\beta_y \bar{\sigma}_2 - \bar{\sigma}_1)|_{(\bar{s}_y, \bar{b}_y) = (\bar{s}_y(\bar{y}), \beta_y \bar{y})} > 0.$$

Assumption (10) is hard to interpret directly. Obviously it implies a limitation on the extent of externalities, since  $\beta_y \bar{\sigma}_2 - \bar{\sigma}_1 < 0$ . It would be implied, given assumption (5), if we assumed that an increase in market demand, accompanied by a corresponding increase in buying effort by households, would not generate so large an external benefit on firms that they could meet this increase without an increase in selling effort; that is, if we assumed that  $\bar{s}_y' > 0$ . For, in that case, (5) and (6) would imply that  $1 + \bar{\sigma} + \bar{y}(\beta_y \bar{\sigma}_2 - \bar{\sigma}_1) = (1 - \bar{y} \bar{\sigma}_1) + (\bar{\sigma} + \bar{y} \beta_y \bar{\sigma}_2) = (1 - \bar{y} \bar{\sigma}_1)(1 + \bar{s}_y'(\bar{y})) > 0$ .

It follows from (5), (9) and (10) that

$$(11) \quad 1 + \sigma(\bar{y}) + \bar{y} \sigma'(\bar{y}) = \frac{1 + \sigma + \bar{y}(\beta_y \bar{\sigma}_2 - \bar{\sigma}_1)}{1 - \bar{y} \bar{\sigma}_1} > 0.$$

An example satisfying all the above conditions is the function:

$$(12) \quad \bar{\sigma}(s, b) \equiv (1 + \beta_y s/b) e^{-(\mu/\beta_y)b}, \quad \mu > 0$$

which yields

$$(13) \quad \sigma(\bar{y}) \equiv e^{-\mu \bar{y}} / (1 - e^{-\mu \bar{y}}).$$

An analogous treatment of the costs of buying and selling labor leads to the per unit cost of selling,  $\tau(\bar{n})$ , where  $\bar{n}$  is the quantity of labor services traded in the market, and  $\tau$  is measured in units of labor. Assume that all transaction costs in the labor market are incurred in the form of labor services used up. I shall interpret unemployment as labor services used up in the selling of labor services. The market quantity of unemployment is  $\bar{s}_n = \tau(\bar{n})\bar{n}$ , and the rate of unemployment is the fraction of all labor services used in selling labor:<sup>11</sup>

$$(14) \quad u(\bar{n}) \equiv \frac{\bar{s}_n}{\bar{s}_n + \bar{n}} = \frac{\tau(\bar{n})}{1 + \tau(\bar{n})}.$$

As with  $\sigma$ , the per-unit cost of selling labor satisfies

$$(15) \quad \tau(\bar{n}) > 0, \quad \tau'(\bar{n}) < 0, \\ 1 + \tau(\bar{n}) + \bar{n}\tau'(\bar{n}) > 0.$$

Therefore the rate of unemployment and the level of employment are inversely related:

$$(16) \quad u'(\bar{n}) = \tau'(\bar{n})/(1 + \tau(\bar{n}))^2 < 0.$$

The cost of buying  $n$  units of labor is  $b_n = \beta_n n$ , for some constant  $\beta_n \in (0, 1)$ .

To sell  $y$  a firm must produce  $y(1 + \sigma(\bar{y}))$ . If it hires  $n$  it can use  $n(1 - \beta_n)$  in production. It therefore chooses  $n$  to maximize its

profit:

$$f(n(1 - \beta_n))/(1 + \sigma(\bar{y})) - wn,$$

where  $w$  is the real wage and  $f$  a production satisfying

$$(17) \quad f'(x) > 0; f''(x) < 0 \quad \text{for all } x > 0;$$

$$\lim_{x \rightarrow 0} (f(x), f'(x)) = (0, \infty);$$

$$\lim_{x \rightarrow \infty} (f(x), f'(x)) = (\infty, 0).$$

Given any  $(w, \bar{y})$  the firm's demand for labor is uniquely determined by the first-order condition:

$$(18) \quad w = \frac{1 - \beta_n}{1 + \sigma(\bar{y})} f'(n(1 - \beta_n)),$$

which can be solved for the demand-for-labor function  $n^d(w, \bar{y})$ , with

$$(19) \quad n^d > 0, \quad n_1^d < 0, \quad n_2^d > 0.$$

Note that this demand function depends not only upon the real wage, but also upon the realized quantity of aggregate demand,  $\bar{y}$ . This is because, in order to formulate its plans, the firm must know the per unit cost of selling output, which depends upon aggregate demand; as in the Barro-Grossman model, the firm must receive quantity signals as well as price signals.

As Clower pointed out, this dependency of demand upon realized quantities is what distinguished Keynes' concept of effective demand from the Walrasian concept of notional demand. But the present derivation of the effective demand for labor does not require firms to make unrealistically pessimistic conjectures. Although they take the quantity demand per firm as given, they see themselves as able to sell more if they wish at the going price, as long as they are willing to pay the marketing cost. An increase in aggregate demand for output raises the demand for labor even with no change in the real wage, not because it raises the maximum

<sup>11</sup>Interpreting (14) as the rate of unemployment requires one to identify  $\bar{n}$  as not only the quantity traded but also the quantity employed. This is required again when  $\bar{n}$  is used as the argument of a production function. I am thus abstracting from one of the most important implications of Okun's "Toll" model, namely that the costly trades in the labor market are new matches. Thus transaction costs would perhaps better be described as a function of the rate of increase in employment. This timeless model might be interpreted as describing stationary quantities chosen by households and firms who realize that more employment will, in the stationary state, imply more turnover (because, say, job separations occur at some exogenous proportional rate), and hence more new matches to be formed. Obviously a fuller treatment of time is required for an adequate treatment of this issue.

amount a firm can sell, but because it makes any given amount of output easier to sell.<sup>12</sup>

Each household's utility function has the form  $U(z, m) - c(l)$ , where  $z$  is consumption,  $m$  is demand for real money balances, and  $l$  is supply of labor. Assume that  $U$  is homogeneous of degree one with indifference curves that do not touch the axes. Assume also that there is an upper limit  $\bar{l} > 0$  to each household's potential labor supply and that the cost function  $c$  is defined over the interval  $[0, \bar{l}]$ , with

$$(20) \quad c'(l) > 0 \text{ and } c''(l) > 0 \\ \text{for all } l \in (0, \bar{l}); \\ c'(0) = 0 \text{ and } \lim_{l \rightarrow \bar{l}} c'(l) = \infty.$$

The assumptions of homogeneity and additivity eliminate income effects from labor supply and permit a diagrammatic analysis similar to Figure 1.

The household that buys  $y$  and sells  $n$  gets to consume  $y(1 - \beta_y)$  and must supply  $n(1 + \tau(\bar{n}))$ . Thus the household's decision problem is to choose  $y$ ,  $m$  and  $n$  so as to maximize  $U(y(1 - \beta_y), m) - c(n(1 + \tau(\bar{n})))$  subject to the budget constraint  $y + m = wn + \pi + M/P$ , where  $\pi$  is the household's profit income,  $M$  the supply of money, and  $P$  the price level, all of which the household takes as given. In equilibrium,  $m = M/P$  so that  $y$  and  $M/P$  must satisfy the marginal condition

$$(21) \quad U_1(y(1 - \beta_y), M/P)(1 - \beta_y) \\ = U_2(y(1 - \beta_y), M/P).$$

Given any  $(w, \bar{n})$  the household's supply of

labor is uniquely determined by the marginal condition

$$(22) \quad w = c'(n(1 + \tau(\bar{n}))) (1 + \tau(\bar{n})) / \lambda,$$

where  $\lambda$  is the value of  $U_2$  when (21) is satisfied. Homogeneity implies that  $\lambda$  is a constant. Equation (22) can be solved for the "effective" supply-of-labor function  $n^s(w, \bar{n})$ , with

$$(23) \quad n^s > 0, \quad n_1^s > 0 \quad n_2^s > 0.$$

The dependency of labor supply upon the realized demand for labor,  $\bar{n}$ , arises because an increase in  $\bar{n}$  reduces the per unit cost of selling labor. Since  $\bar{n}$  is inversely related to the rate of unemployment (16), therefore the dependency of labor supply upon  $\bar{n}$  is operationally the same as the "discouraged worker" effect.

An equilibrium is defined as a triple  $(w, n, y)$  such that

$$(24) \quad n^d(w, y) = n^s(w, n),$$

$$(25) \quad n = n^s(w, n),$$

$$(26) \quad y(1 + \sigma(y)) = f(n(1 - \beta_n)).$$

Equation (24) is the usual labor market equilibrium condition. But equilibrium requires also that the quantity signals to which the agents are responding correspond to the actual market quantities. Thus (25) requires the quantity of labor taken as given by the household to equal the equilibrium quantity, and (26) requires the sales quantity taken as given by firms to equal the equilibrium quantity; that is the amount produced  $f(n(1 - \beta_n))$  minus the amount used up in marketing  $y\sigma(y)$ . (I now omit bars from market quantities.) Given the equilibrium values of these variables, the price level satisfying (21) will equate  $y$  with the demand for output.

The equilibrium condition (26) can be rewritten in the following way. First define the function  $q(y) \equiv (1 + \sigma(y))y$ . This function indicates the amount of production required to market any given quantity of sales. By (9)

<sup>12</sup>In this sense the model is similar to the stochastic manipulable rationing model of Lars Svensson (1980), in which the cost to an agent of trying to exceed his allocated ration is that he might be forced to make the proposed trade. The difference is that, in Svensson's model, the rationing process uses up no resources whereas in this model it is costly to propose trades. In both cases one ends up with an alternative concept of effective demand.

and (11),

- (27) For all  $y > 0$ ,  $q(y)$  is continuous,  
strictly increasing, with  $q(y) > y$ .

Next, define  $\underline{q} \equiv \lim_{y \rightarrow 0} q(y) \geq 0$ , and  $\underline{n} \equiv (1 - \beta_n)^{-1} f^{-1}(\underline{q}) \geq 0$  (where  $f^{-1}(0) \equiv 0$ ). Then  $\underline{q}$  is the minimal amount of output needed to market any sales at all, and  $\underline{n}$  the corresponding amount of employment. Note that  $\underline{q}$  is well defined, by (27), that  $\underline{n}$  exists, by (17), and that  $\underline{n} = 0$  if and only if  $\underline{q} = 0$ , by (17).

Next I show that given  $n$ , (26) has a solution  $y > 0$  if and only if  $n > \underline{n}$ . To show this suppose first that  $n \leq \underline{n}$ . Then, by (17) and (27)  $f(n(1 - \beta_n)) \leq f(\underline{n}(1 - \beta_n)) \equiv \underline{q} < q(y)$  for all  $y > 0$ , so (26) has no such solution. Next suppose that  $n > \underline{n}$ . Then by (17) and (27):

$$\lim_{y \rightarrow 0} q(y) \equiv f(\underline{n}(1 - \beta_n)) < f(n(1 - \beta_n))$$

$$< \infty = \lim_{y \rightarrow \infty} q(y).$$

So, by Roll's theorem and the continuity of  $q(\cdot)$ , there is a solution to (26) with  $y > 0$ .

Finally note that, since  $q(\cdot)$  is strictly increasing, the implicit function theorem implies that (26) defines a function  $\bar{y}(n)$  for all  $n > \underline{n}$  and that

$$(28) \quad \bar{y}'(n) = (1 - \beta_n) f' / q'$$

$$= \frac{(1 - \beta_n) f'}{1 + \sigma + y \sigma'} > 0,$$

$$(29) \quad \lim_{n \rightarrow \underline{n}} \bar{y}(n) = \lim_{n \rightarrow \underline{n}} q^{-1}(f(n(1 - \beta_n)))$$

$$= \lim_{x \rightarrow \underline{q}} q^{-1}(x) = 0.$$

The function  $\bar{y}(\cdot)$  indicates the level of sales that can feasibly be marketed given any amount of employment greater than the minimal amount  $\underline{n}$ . Condition (26) is equivalent to the condition:  $y = \bar{y}(n)$ .

I can now reduce the definition of equilibrium to one involving a single equation in

FIGURE 2

$n$ . From the definitions of  $n^d$  and  $n^s$ ,  $(w, n, y)$  is an equilibrium if and only if  $n$  satisfies

$$(30) \quad \frac{1 - \beta_n}{1 + \sigma(\bar{y}(n))} f'(n(1 - \beta_n))$$

$$= (1 + \tau(n)) c'(n(1 + \tau(n))) / \lambda,$$

$w$  equals the common value of either side of (30), and  $y = \bar{y}(n)$ . The two sides of (30) are the demand price and supply price for  $n$  units of labor, represented by  $D$  and  $S$  in Figure 2.

Because of the externalities, the equilibrium will not generally be unique. To see this suppose first that there were no externalities—that  $\sigma$  and  $\tau$  were constant. Then the usual labor market equilibrium condition (24) would be sufficient to determine the equilibrium level of employment, without the quantity equations (25) and (26), because  $n^s$  and  $n^d$  would depend only upon  $w$ . This equilibrium condition would be equivalent to (30) with  $\sigma$  and  $\tau$  constant. Equilibrium would be unique because the assumptions of declining marginal product (17) and rising marginal disutility (20) of labor would guarantee that the demand price was decreasing and the supply price increasing in  $n$ . This is illustrated by  $D'$  and  $S'$  in Figure 2, along which  $\sigma$  and  $\tau$  equal  $\sigma(\bar{y}(n_H))$  and

$\tau(n_H)$ . But, with the externality,  $D$  can be upward sloping because as employment increases, the unit cost of selling output  $\sigma(\bar{y}(n))$  decreases (from (9) and (28)), which tends to increase the demand price. Likewise  $S$  can be downward sloping because as employment increases, the unit cost of selling labor decreases (from (15)) which tends to lower the supply price. These effects of externalities make it possible for  $D$  and  $S$  to intersect more than once in nonpathological cases.

Indeed it is possible to specify boundary conditions that guarantee multiplicity except in razor's-edge cases. For example, suppose that in order to sell any output at all, firms must produce at least some positive critical mass of output; that is, that  $\underline{q} > 0$  and  $\underline{n} > 0$ . Under this assumption the unit cost of selling rises to infinity as sales fall to zero, and rises so fast that the total cost  $y\sigma(y)$  is bounded away from zero. The example (12) specified above satisfies this assumption.

In order for  $n$  to be the equilibrium level of employment, all the expressions in the equilibrium condition (30) must be well defined. This implies that  $n \geq \underline{n}$ . It also implies that  $n(1 + \tau(n))$  must be less than the upper limit on labor supply  $\bar{l}$ . From (15) the function  $l(n) \equiv n(1 + \tau(n))$  is strictly increasing and positive valued for all  $n > 0$ , with a range  $(l, \infty)$  for some  $l \geq 0$ . Assume that  $l < \bar{l}$ . Then  $\bar{n} \equiv l^{-1}(\bar{l})$  is well defined and the restriction imposed by the limit on labor supply is that  $n$  be less than  $\bar{n}$ .

If  $\underline{n} \geq \bar{n}$ , then no equilibrium is possible. So suppose that  $\underline{n} < \bar{n}$ . Then the equilibrium level of employment must lie in the interval  $(\underline{n}, \bar{n})$ ; there must be enough to get the output market started but no more than can feasibly be supplied. Therefore, to show generic multiplicity, it suffices to show that the supply price exceeds the demand price for values of  $n$  close enough to  $\underline{n}$  and for values close enough to  $\bar{n}$ . If this is so, then in terms of Figure 2 the only way that  $D$  and  $S$  can have a unique point of intersection is for them to be tangent at that point. But this is obviously a razor's-edge case. Generically there will exist an even number of intersections, so that if equilibrium exists it will be nonunique.

To show this, consider first what happens as  $n$  approaches  $\bar{n}$ . Because  $\bar{n} > \underline{n} > 0$ , the demand price remains bounded. But  $n(1 + \tau(n)) \equiv l(n)$  approaches  $l(\bar{n}) \equiv \bar{l}$  so that, by (20), the supply price becomes infinite. Next suppose  $n \rightarrow \underline{n}$ . Because  $\underline{n} > 0$ , (15) and (20) imply that the supply price remains bounded away from zero. Also, from (17),  $f(n(1 - \beta_n)) \rightarrow f(\bar{n}(1 - \beta_n)) > 0$ ; but from (29),  $\lim_{n \rightarrow \underline{n}} (1 + \sigma(\bar{y}(n))) = \lim_{y \rightarrow 0} (1 + \sigma(y)) = \infty$ , so the demand price approaches zero. Therefore the demand price is less than the supply price as  $n$  approaches either limit.

A similar demonstration of generic multiplicity goes through under the alternative assumption that  $\bar{l} \equiv \lim_{n \rightarrow 0} (1 + \tau(n))n > 0$ . Even with both  $\bar{l}$  and  $\underline{q}$  equal to zero a similar demonstration can be constructed under the assumption that

$$\lim_{n \rightarrow 0} [(1 + \tau(n))c'(n(1 - \tau(n))) \\ (1 - \sigma(\bar{y}(n)))] \\ / [\lambda(1 - \beta_n)f'(n(1 - \beta_n))] > 1.$$

Another consequence of the externalities is that not all gains from trade are fully exploited in an equilibrium even if it is unique. Specifically, suppose firms were to hire a small amount more labor at the same wage, and the price level were to adjust so as to allow the resulting increase in output to be sold. Consider what would happen to the typical firm's profit:  $f(n(1 - \beta_n))/(1 + \sigma(\bar{y}(n))) - wn$ . If there were no externalities (i.e., if  $\sigma$  were constant) then the firm's marginal condition (18) would imply that profit would remain unchanged. But, with the externalities,  $\sigma$  would fall, so profit would increase. Next, consider the level of household utility. If  $\sigma$ ,  $\tau$ , and  $m$  were constant, then according to (28)  $y$  would change at the rate  $dy/dn = (1 - \beta_n)f'/(1 + \sigma)$ , which by the firm's marginal condition equals the wage  $w$ ; the change in household utility would therefore be  $(1 - \beta_n)U_y w - (1 + \tau)c'$ , which, by the marginal condition (22) and the definition of  $\lambda$ , equals zero. But, with the externality,  $\sigma$  and  $\tau$  would decrease. The decrease in  $\sigma$  would make  $y$  increase by more than  $w$ . The decrease in  $\tau$  would make the disutility of

labor rise by less than  $(1 + \tau)c'$ . Furthermore, the change in the price level would have to keep the marginal condition (21) satisfied, which by homogeneity would require real balances  $m$  to equal  $k\bar{y}(n)$  for some constant  $k$ . Therefore  $m$  would increase. Thus taking into account the externalities and the change in  $m$ , utility would increase. Both firms and households would gain.

The following argument shows that, if there are multiple equilibria, household utility will be strictly greater whenever employment is greater. Consider any two equilibria,  $n_0$  and  $n_1$ , each satisfying (30), with  $0 < n_0 < n_1$ . Define

$$\phi(n) \equiv U(\bar{y}(n)(1 - \beta_y), k\bar{y}(n)) - c(n(1 + \tau(n))).$$

I want to show that  $\phi(n_0) < \phi(n_1)$ . Next, define

$$\Psi(n) \equiv \max_{\{x\}} U\left(f(x(1 - \beta_n)) \frac{1 - \beta_y}{1 + \tau(\bar{y}(n))}, k\bar{y}(n)\right) - c(x(1 + \tau(n))).$$

The first-order condition uniquely defining the solution to this problem is

$$U_1\left(f(x(1 - \beta_n)) \frac{1 - \beta_y}{1 + \sigma(\bar{y}(n))}, k\bar{y}(n)\right) \cdot f'(x(1 - \beta_n)) \frac{(1 - \beta_y)(1 - \beta_n)}{1 + \sigma(\bar{y}(n))} - c'(x(1 + \tau(n)))(1 + \tau(n)) = 0,$$

which is satisfied by  $x = n$  whenever  $n$  satisfies (30). Thus  $\Psi(n) = \phi(n)$  whenever  $n$  satisfies (30). Furthermore, for all  $n > 0$ ,

$$\Psi'(n) = -\left[\sigma' \cdot \bar{y}' \cdot f \cdot (1 - \beta_y) / (1 + \sigma)^2\right] U_1 + k\bar{y}' U_2 - \tau' \cdot x \cdot c' > 0.$$

Therefore,  $\phi(n_0) = \Psi(n_0) < \Psi(n_1) = \phi(n_1)$ .

By (16) the rate of unemployment will be lower whenever employment is greater. But what happens to the total amount of unemployment  $n\tau(n)$  as employment increases cannot be predicted.

#### IV. Comparison to the Keynesian Account

The preceding example shows how transaction costs and the externality of thin markets might account for persistently high rates of unemployment. Under any of the boundary conditions discussed, or more generally whenever multiple equilibria exist, the economy could shift permanently from one equilibrium to another with a lower level of employment and a higher rate of unemployment. How such shifts might be initiated and what course they would take can't be analyzed with this static model. But the model predicts that increases in unemployment can persist indefinitely.

The example has several Keynesian features, all of which are attributable to the fact that each agent is affected directly by the quantities  $\bar{n}$  and  $\bar{y}$  chosen by others. First, as we have seen, these direct effects are the reason why the example exhibits Keynesian "effective" demand and supply functions for labor.

Second, in the case of multiple equilibria the model exhibits a reciprocal feedback between labor and output markets similar to that involved in the Keynesian multiplier process. Consider a shift from  $n_H$  to  $n_L$  in Figure 2. This can be described as leftward shifts in the "constant-selling-cost" demand and supply functions to  $D''$  and  $S''$ . The level of aggregate demand declines because of the decline in employment (from  $\bar{y}(n_H)$  to  $\bar{y}(n_L)$ ). Conversely, employment declines at least in part because of the leftward shift in labor demand, which is caused by the decline in aggregate demand  $\bar{y}$ .

The case of multiple equilibria highlights another Keynesian feature;<sup>13</sup> namely, that the example is consistent with no discernible

<sup>13</sup>"Keynesian" in the sense of the account described in Figure 1. Keynes' *General Theory* actually implies countercyclical wages.

cyclical pattern to real wages. It is obviously possible for the real wage to be the same in the two equilibria of Figure 2, in which case employment can fluctuate (between  $n_L$  and  $n_H$ ) with no change in the real wage.

Another Keynesian feature is the result that not all gains from trade will be fully exploited in equilibrium. We saw that, as in the Keynesian account, firms would willingly hire more workers if they thought that aggregate demand would go up by as much as the net supply of output; but they have no incentive to do so because they take the level of aggregate demand as given.

Finally, it can be argued that the unemployment exhibited by the model is involuntary, as in Keynesian economics, despite the flexibility of wages. As Don Patinkin (1965, pp. 313–15) has argued, “involuntary” must mean chosen subject to an “unusually severe” constraint. By this criterion the unemployment in our example is involuntary in two distinct senses. First, in addition to the “usual” budget constraint workers are subject to a constraint requiring so much time to be spent in unemployment for every hour worked. Although each household is choosing to incur the amount  $n\tau(\bar{n})$  of employment, this choice is not being made as a substitute for employment as it would be if there were only the budget constraint. In this sense all unemployment in the example is involuntary.

In principle there is, however, no reason to think of the constraints imposed by transaction costs as being any less “usual” than the budget constraint. Still there is a sense in which at least some of the unemployment in a low-level equilibrium ( $n_L$  in Figure 2) fits Patinkin’s criterion of involuntariness. For, in this equilibrium, the transaction-cost constraint could be regarded as “unusually severe.” In order to sell  $n_L$  units of labor, the household is required to spend the amount  $n_L\tau(n_L)$  in unemployment instead of the smaller amount  $n_L\tau(n_H)$  that would be required to sell this much if the economy were at its high-level equilibrium. Thus the amount  $n_L(\tau(n_L) - \tau(n_H))$  might be regraded as involuntary. If we interpret these increased costs along the lines suggested by Okun’s analysis as the increased difficulty of

finding potential employers who are actively hiring, then they are indeed what observers of labor markets in depression refer to when describing the rise in unemployment as involuntary.

The example thus shows that it is possible to develop an account of unemployment with several Keynesian features, based upon the externalities of transaction costs, without some of the shortcomings of the Keynesian account. Specifically, the example does not require an assumption of unrealistically pessimistic sales conjectures as a foundation for its concept of effective demand, and it avoids the dilemma of basing a theory of “involuntary” unemployment on the refusal of the unemployed to work for less than the going wage.

This is not to say that the example provides a restatement of Keynesian economics. Among the Keynesian elements missing from it is any role of the marginal propensity to consume in the multiplier process. Nor is the model as it stands able to explain how changes in the level of aggregate demand, whether exogenous or induced by monetary or fiscal policy, could affect the level of output. In particular, money is neutral in the model, in the sense that all equilibria remain invariant in real terms to changes in  $M$ . Such changes might propel the economy from one real equilibrium to another, but the model as it stands has no dynamics with which to address the question. Nor is the model consistent with the Keynesian implication that, within some interval, any level of employment is consistent with equilibrium under the same tastes and technology. Furthermore the assumption of perfectly flexible wages and prices makes it inconsistent with Keynesian explanations of the slow adjustment of nominal wages and prices.

## V. Conclusions

Quantity adjustments are often seen as substitutes for price adjustments in Keynesian economics. If prices were perfectly flexible transactors would not have to be informed of realized quantities in order to formulate mutually consistent trading plans; they would just need to observe prices that

had been adjusted to their equilibrium values. If prices were inflexible transactors would also have to know realized quantities, which would have to be adjusted to their fixed-price equilibrium values. Patinkin (1976, especially pp. 65–66) has identified the essential contribution of Keynes' *General Theory* as the analysis of the equilibrating role of such quantity adjustments.

The example presented in this paper suggests that if there are significant external economies operating through transaction costs, quantity and price adjustments may be complements, not substitutes. Even with perfectly flexible prices, transactors must know the equilibrium values of realized quantities in order to formulate mutually consistent plans. The quantity signals to which they respond must satisfy the consistency conditions (25) and (26). Because many of the essential features of the Keynesian account of persistent unemployment follow from this need for quantity adjustment, they will be exhibited even in models with fully flexible prices.

None of this implies that perfect price flexibility is a good assumption, or that the issue of price flexibility has little quantitative importance for understanding fluctuations in unemployment. But it suggests that the issue of price flexibility is not crucial to many Keynesian results. When the transaction costs that are implicit in Keynesian analysis are made explicit, these results go through regardless of the degree of price flexibility. It also suggests, therefore, that from a Keynesian perspective a deeper understanding of unemployment will come from paying more attention to these transaction costs rather than attaching to "sticky prices" the blame for all communication problems in the economy.<sup>14</sup>

Future research along these lines will obviously require a more explicit treatment of price formation, along with a more explicit account of the institutional arrangements underlying the cost of transacting.

<sup>14</sup> Joseph Ostroy (1973) gives a graphic description of the communication problems that would remain even if an auctioneer costlessly computed and announced equilibrium prices.

# The Demand for Unobservable and Other Nonpositional Goods

By ROBERT H. FRANK\*

The importance of demonstration effects in consumption behavior has long been recognized by economists and other social scientists.<sup>1</sup> But such demonstration effects by their very nature cannot apply with equal force to all categories of goods. We may know very well, for example, what kinds of cars acquaintances drive or the types of homes they live in, but we are much less likely to know how much they save or the amounts they spend on insurance.

Even in circumstances where what others consume is known, interpersonal comparisons with respect to certain *types* of consumption will be more important than will others. As Thorstein Veblen emphasized in 1899, at least some people appear actively concerned about how the amount of leisure they consume compares with the amounts consumed by their peers. But for most people, we may safely assume that such comparisons pale in relation to the corresponding comparisons regarding, say, the education of their children.

Following Fred Hirsch (1976, ch. 3), I use the term "positional goods" here to mean those things whose value depends relatively strongly on how they compare with things owned by others. Goods that depend relatively less strongly on such comparisons will be called nonpositional goods. As noted, the nonpositional category includes, but is not limited to, goods that are not readily observed by outsiders. This paper explores how patterns of spending behavior are affected by the fact that interpersonal comparisons apply

with greater force to some goods than to others.

Section I begins with an example that illustrates why interpersonal comparisons are more important for some goods than for others. This example also illustrates, in a qualitative way, the conclusion that noncooperative consumption decisions result in an underconsumption of nonpositional goods.

Section II then describes a formal model in which rank effects produce downward distortions in individual demands for nonpositional goods. Under certain circumstances, collective restrictions on consumption behavior are shown to produce welfare improvements, even for fully rational consumers operating in structurally competitive environments. Budget shares for certain nonpositional goods are shown to vary systematically with income and with the access individuals have to mechanisms for implementing cooperative consumption agreements.

Section III further explores the adaptive significance of imitative behavior. Such behavior is shown to be individually adaptive, but collectively maladaptive, in the context of a signaling competition in which observable consumption goods help identify individuals of high ability.

Section IV summarizes a variety of empirical evidence that bears on the hypotheses put forward in Sections I and II. This evidence suggests that James Duesenberry's relative income hypothesis (1949) was abandoned prematurely by the economics profession. It also suggests an alternative interpretation of the economic role of the trade union.

The paper concludes by noting that forced savings programs, safety regulation, overtime laws, and various other regulations of the labor contract may be interpreted as devices for mitigating the consequences of competi-

tions between workers for favored positions in the income hierarchy. The apparent strength of consumption externalities suggests that supply siders are barking up the wrong tree when they say that income and consumption taxes introduce distortions into important economic decisions. Rather, such taxes alleviate existing distortions in those same decisions.

### I. Individual Consumption Decisions when Relative Standing Matters

In my 1985 study (ch. 2), I have argued that useful insights into people's economic behavior are afforded by the view that the utility function (or what psychologists would call the structure of motivation) was shaped by the forces of natural selection. By this view, the human nervous system is hard-wired with a panoply of tastes and aversions that contribute (or once contributed) to the individual's reproductive fitness. Sugar tastes sweet to us, for example, because having had an affinity for ripened fruit once contributed significantly to our primate ancestors' capacities to survive and leave offspring.

A more general implication of this view is that an element of almost overriding importance in the structure of human motivation will be a taste for seeing to it that one's children are launched in life as successfully as possible. Now, how successful one's children will be in life depends much less on their skills and endowments in any absolute sense than on how these compare with the skills and endowments of others. Success in the labor market, for example, depends much less on the quality of instruction one receives, *per se*, than on how one's training compares with the training received by others.<sup>2</sup> Suppose we take as a working hypothesis that a parent's utility function is programmed with an instruction something like, "Feel bad whenever your children are less well provided for than are the children of your peers." What sorts of behavior would

such a utility function predict that would not be predicted by the utility functions that economists generally work with?

To pursue this question, consider an example in which two persons, *A* and *B*, are each faced with the choice of working in a clean mine or a dusty mine. Wages in the clean mine at \$200 a week are lower than those in the dusty mine by \$50, an amount that reflects the cost of maintaining a dust-free working environment. The lone adverse consequence of working in the dusty mine is that life expectancy is shortened by fifteen years.

If *A* is strongly concerned about where his children stand vis-à-vis *B*'s (with respect to education and various other advantages), and if *B* feels that same concern, then the payoff to each from working in a given mine will depend in a clear way on the mine chosen by the other. In choosing between the two mines, each must weigh not only his feelings about the value of extended longevity in the abstract, but also the fact that his choice will affect his ranking in the income hierarchy. Suppose the two rank the four possible outcomes in the way shown in Table 1.

The rankings in the upper-left and lower-right cells of Table 1 indicate that, in the absence of concerns about the relative standing, each would find it worthwhile to sacrifice \$50 a week in order to escape working in the dusty mine. But neither is willing to make that same exchange if in the process he loses ground in the income hierarchy. As the rankings are configured here, *A* and *B* confront a standard example of the prisoner's dilemma. The dominant strategy for each is to choose the dusty mine. Yet, by so doing, an outcome results that each finds distasteful in comparison with the (feasible) alternative of both working in the clean mine.

If preferences were indeed forged in the crucible of natural selection, it is easy to see why people might find it attractive to sacrifice longevity in return for an opportunity to provide decisive advantages for their children (or in order to prevent their children from becoming seriously disadvantaged in a relative sense). Yet the number of favored positions in any rank ordering is fixed inescapably by the laws of simple arithmetic. And

<sup>2</sup>See for example, A. Michael Spence (1974), Hirsch, and Lester Thurow (1975).

TABLE 1—MINE SAFETY CHOICES WHEN  
RELATIVE STANDING MATTERS

A	B	
	Clean Mine	Dusty Mine
Clean Mine	Second best for A Second best for B	Worst for A Best for B
Dusty Mine	Best for A Worst for B	Third best for A Third best for B

Note: Clean mine: \$200 a week; Dusty mine: \$250 a week.

thus the exchange that is so attractive from each individual's point of view has no similar allure when viewed from the perspective of the population as a whole.

A related distortion is present when individuals make decisions about how much leisure to consume. To the extent that extra income is valued not only for its own sake, but also for the *relative* advantages it affords, the option of working an additional hour will appear misleadingly attractive to individuals.<sup>3</sup> Conventional economic analysis shows the workweek that emerges in an atomistically competitive labor market to be Pareto optimal, but when relative standing is a primary concern, this result no longer holds. For the perceived individual payoffs from the sale of leisure will then add up to more than the realized aggregate payoff.

Such distortions as these need not be viewed as having arisen because people are concerned about relative standing per se. As Hirsch, Amartya Sen (1983), and others have emphasized, having high relative standing is *instrumental* to the realization of numerous legitimate human objectives.<sup>4</sup> Disdainful attitudes towards people's efforts to "keep up with the Joneses" should not be allowed to obscure the fact that concerns about relative standing are completely consistent with the rational pursuit of self-interest.

<sup>3</sup>Duesenberry makes a similar point. See also Richard Layard (1980) and Michael Boskin and Eytan Sheshinski (1978).

<sup>4</sup>See also my 1985 study.

## II. A Simple Model of the Demand for Nonpositional Goods

Though the characteristics of consumption goods clearly vary continuously along many different dimensions, it will be convenient for analytical purposes to think of goods as falling into one of two classes, positional goods and nonpositional goods. Let us assume an individual's utility is determined by how much of each type of good he has and how his consumption compares with the consumption of others. Interpersonal comparisons matter, by definition, only with respect to positional goods. Specifically, let us assume a population of individuals in which all have identical utility indexes,

$$U = U(x, y, R(x)),$$

where  $x$  = positional consumption level,  $y$  = nonpositional consumption level, and  $R(x)$  is a number between 0 and 1 indicating the percentile ranking of  $x$  in the population of  $x$  values. If  $f(x)$  represents the density function for  $x$  values and  $x_0$  is the smallest value taken by  $x$  in the relevant population, then an individual with  $x = x_1$  will have

$$(1) \quad R(x_1) = \int_{x_0}^{x_1} f(x) dx.$$

When individuals are spoken of below as making consumption decisions noncooperatively, this will mean that they make the Nash-Cournot assumption that their own spending behavior does not perceptibly alter the spending behavior of others. That is, noncooperative consumption demands are defined as those that emerge when individuals maximize utility taking the density  $f(x)$  as being externally fixed.

The first-order conditions for the utility maximization exercise here are

$$(2) \quad (U_1/U_2) + (U_3/U_2)R'(x) = P_x/P_y,$$

and

$$(3) \quad P_x x + P_y y = M,$$

where  $U_i$  is the partial derivative of  $U$  with respect to its  $i$ th argument,  $P_x$  and  $P_y$  are the prices of  $x$  and  $y$ , and where  $M$  is income, which is exogenously given for each individual. Equation (1) says that  $R'(x) = f(x)$ , so equation (2) may be rewritten as

$$(2') \quad (U_1/U_2) + (U_3/U_2)f(x) = P_x/P_y.$$

Against the equilibrium condition given in (2'), let us now contrast the solution that emerges when individuals maximize utility by acting cooperatively. First we must specify what purpose cooperative behavior is meant to achieve in this context. In equation (2') we see that when individuals act noncooperatively, each perceives that additional consumption  $x$  augments utility not only through its direct effect,  $U_1$ , but also through its indirect effect on the rank term,  $R(x)$ . Yet the assumption of identical utility indexes assures that once the noncooperatively determined equilibrium is reached, each individual's ultimate ranking in the positional goods hierarchy will be the same as his original ranking in the exogenously given income hierarchy. Viewed from the perspective of the collective, the second, indirect return to positional goods consumption is thus entirely spurious.

Let us assume, therefore, that the objective of the cooperating population is to eliminate the influence of this spurious return from individual consumption decisions. If  $g(m)$  represents the original density function of income values and  $m_0$  the smallest income level in the population at issue, a natural way of accomplishing this objective is for each individual to allocate his income  $M$  across  $x$  and  $y$  as he would if his rank in the positional goods hierarchy were taken to be fixed in advance at

$$(4) \quad R(x) = \int_{m_0}^M g(m) dm = G(M).$$

That is, let us assume that the cooperative case may be thought of in terms of a collection of individual maximization problems of

the form

$$(5) \quad \max_{x,y} U(x, y, G(M)),$$

$$\text{subject to} \quad P_x x + P_y y = M.$$

Equation (5) is, of course, the same as the simple utility maximization problem from the traditional independent preferences setting, and its first-order conditions are thus

$$(6) \quad U_1/U_2 = P_x/P_y,$$

with the same budget constraint as in equation (3).<sup>5</sup>

Comparing the equilibrium equations (2') and (6), the following propositions may be easily established:

**PROPOSITION 1:** *Cooperatively determined demands will be higher for nonpositional goods and lower for positional goods than the corresponding demands determined noncooperatively.*

**PROPOSITION 2:** *Each individual's utility level will be higher in the case of cooperatively determined demands than in the case of noncooperatively determined demands.*

Both of these propositions reflect the fact that the presence of  $R(x)$  in the utility function acts as an implicit subsidy to positional goods consumption in the noncooperative case, with the usual attendant consumption distortions and welfare reductions.

Using the notation  $E_{U_i}$  to represent the elasticity of  $U$  with respect to its  $i$ th argument, and  $E_{R_x}$  to represent the elasticity of  $R(x)$  with respect to  $x$ , equations (2') and (6) can be rewritten as

$$(2'') \quad (y/x)(E_{U_1}/E_{U_2} + (E_{U_3}/E_{U_2})E_{R_x}) = P_x/P_y,$$

<sup>5</sup> It is easily shown that the allocation that emerges in the cooperative case lies in the core.

and

$$(6') \quad (y/x)(E_{U1}/E_{U2}) = P_x/P_y.$$

In populations in which  $x_0$ , the smallest value of  $x$ , exceeds zero,  $E_{R_x}$  will be infinite at  $x_0$  and, for any  $f(x)$  likely to be observed in practice, decline monotonically to zero as  $x$  moves toward the maximum value in its domain. Let us suppose that  $E_{R_x}$  behaves in this fashion, and let  $y = \lambda(x)$  represent the income expansion path that obtains for the cooperative case. Then, for all utility functions for which  $(E_{U3}/E_{U2})E_{R_x}$  is a decreasing function along  $y = \lambda(x)$  (a very unrestrictive condition, since  $E_{R_x}$  declines monotonically from  $\infty$  to 0 along that path), we may easily demonstrate

**PROPOSITION 3:** *Budget shares for nonpositional goods grow more rapidly (or decline less rapidly) with income in the noncooperative than in the cooperative case.*

As a special case of Proposition 3, let us consider the nonpositional good "savings," and suppose that, except for the influence of rank effects, savings behavior would be governed by the forces contemplated in either the permanent income or life cycle hypotheses of savings. That is, holding  $R(x)$  fixed, suppose that  $U(x, y, R(x))$  is homothetic in  $x$  and  $y$ , where  $x$  is now consumption and  $y$  is savings. With  $R(x)$  fixed, budget shares devoted to savings will then be constant across income levels. This means that Proposition 3 can be restated as

**PROPOSITION 3':** *Noncooperative budget shares for savings are an increasing function of the individual's rank in the income hierarchy of the population of which he is a member.*

To go further in assessing the quantitative differences between noncooperative and cooperative demands, let us impose additional restrictions on the form of the utility index,  $U$ . The Cobb-Douglas form has the homothetic property assumed for the savings example, and is analytically convenient.

Specifically, let

$$(7) \quad U(x, y, R(x)) = x^{\alpha_1} y^{\alpha_2} (R(x))^{\alpha_3},$$

where  $\alpha_1, \alpha_2$ , and  $\alpha_3 > 0$ .

Using equation (7), the first-order conditions for a maximum in the noncooperative case are given by the budget constraint from equation (3) and by

$$(8) \quad \alpha_1 y / \alpha_2 x + \alpha_3 y f(x) / \alpha_2 R(x) = P_x / P_y.$$

For illustrative purposes, suppose the density  $f(x)$  is uniform on the interval  $[x_0, Kx_0]$ , where  $K$  is some positive integer. Using this form for  $f(x)$ , equation (8) becomes

$$(9) \quad \alpha_1 y / \alpha_2 x + \alpha_3 y / \alpha_2 (x - x_0) = P_x / P_y, \\ \text{for } x \in [x_0, Kx_0].$$

The corresponding first-order condition for the cooperative case is simply

$$(10) \quad \alpha_1 y / \alpha_2 x = P_x / P_y.$$

Whether the demand functions that emerge from the cooperative case differ substantially from the corresponding noncooperative demand functions is thus seen to depend critically on the magnitude of the parameter  $\alpha_3$ , the elasticity of utility with respect to rank in the positional goods hierarchy. For the particular case in which  $\alpha_1 = \alpha_2 = \alpha_3$ , budget shares for nonpositional goods are as depicted in Figure 1.

As indicated in Figure 1, the budget share for nonpositional goods approaches zero for individuals near the bottom of the positional goods hierarchy, even though the derivative  $\partial U / \partial y$  becomes infinite as  $y$  approaches zero in the Cobb-Douglas form. Though the payoff to consuming  $y$  is very high at small values of  $y$  here, the payoff to additional consumption of  $x$  is even higher because of the advancement it enables in the positional goods hierarchy. That the hoped-for advance does not materialize in the end because of the parallel actions of others makes this con-

FIGURE 1. COOPERATIVE AND NONCOOPERATIVE BUDGET SHARES FOR UNOBSERVABLES

sumption behavior no less purposeful from the perspective of the individual; failure to allocate consumption in this fashion while others do would result in a backward movement in the positional goods hierarchy, hardly a better result under the assumed preference ordering.<sup>6</sup>

Elsewhere I have surveyed available empirical evidence from a number of studies on the comparative contributions to individual happiness levels made by absolute income levels on the one hand, and relative standing

on the other.<sup>7</sup> All of the findings reported in these studies are consistent with the hypothesis that relative standing is far more important than the absolute level of consumption in determining individual well-being. In view of the breadth and consistency of the available evidence on this question, it is far from fanciful to assign a significant role to the relative standing parameter  $\alpha_3$  in equation (7). If the elasticity of utility with respect to relative standing in the consumption hierarchy is considerably greater than that for absolute levels of goods consumption, as all available evidence suggests, the resultant consumption distortions, and their implied welfare consequences, will be even larger than those pictured in Figure 1.

### III. Consumption as a Signal of Ability

In the struggle to see the next generation safely launched, imitative behavior may, as noted in Section I, have individually adaptive consequences. Granted, by spending more on one's child's education today, one's rank in the consumption hierarchy may decline during retirement years. But from each individual's perspective, the decline in future ranking may be more than compensated for by the present gain. (The fact that the sought-after advance in the current rankings cannot be realized collectively is cold comfort to the individual who fails to keep rank today. I have argued elsewhere, 1985, ch. 7, that the divergence between individual and collective payoffs here may help account for what Pigou called the faulty telescopic faculty.)

From the individual's perspective, it does not even follow that consuming more now will necessarily result in diminished future consumption, because the information implicit in present consumption levels may affect future incomes. In societies in which

<sup>6</sup>If people are certain of their rank in the positional goods hierarchy, the model as it is expressed above does not produce a stable outcome. The lowest-ranking member of the hierarchy could initially move past the second lowest-ranking member by increasing his consumption of positional goods; and the second lowest-ranking member could then restore the original ordering by carrying out a similar shift of his own. But then the lowest-ranking member could reduce his consumption of positional goods without adversely affecting his ranking, which would already be as low as it could get. In turn, the second lowest-ranking member could then reduce his consumption of nonpositional goods without penalty, and in like fashion the higher-ranking members would one-by-one have an incentive to follow suit. Their having done so, the cycle would be set to begin anew.

Alternatively, the lowest-ranked member of the hierarchy may not be certain he is lowest ranked, and thus may be reluctant to act as if spending less on positional goods will not adversely affect his ranking. Another simple modification to the model that would generate a stable equilibrium would be to add the plausible assumption that people care not only about their rankings, but also about where they stand vis-à-vis the mean or some other cardinal parameter of the distribution. These modifications complicate the exposition, but do not alter the conclusions stated in Propositions 1-3 above.

<sup>7</sup>See my 1985 study, ch. 2. I have also argued that an implicit market exists for high-ranked positions in the earnings hierarchies we call firms. For all of the specific occupations for which I was able to construct empirical estimates, the implicit price of such positions is a substantial fraction of total earnings (see my 1984 article).

economic and social interactions between individuals are important (which is to say, in every society), information about the others with whom one might interact has obvious value. The mates we choose, the employees we hire, the people whose company we seek—all depend in a clear way on the information we are able to gather about other individuals in our environment. Many of the most important decisions ever made about us turn on others' estimates of what talents, abilities, and other characteristics we possess. Consider a population in which individuals' abilities are known to differ substantially but in which any specific individual's ability cannot be observed directly. Even in a loosely competitive labor market, there will be a strong positive correlation between individual ability and income levels. Similarly, when there is broad dispersion in income levels, there will generally be a strong positive correlation between individual income levels and various observable consumption goods: the size and location of one's home, the quality of one's automobile or wardrobe, the clubs to which one belongs, and so on. When an individual's ability level cannot be observed directly, such observable components of his consumption bundle constitute a signal to others about his total income level, and on average, therefore, about his level of ability.<sup>8</sup>

Let us explore the extent to which imperfect information about ability might create incentives for people to rearrange consumption patterns to favor observable goods. Consider a population of  $N$  individuals with productive ability levels  $A_1, \dots, A_N$ , which cannot be observed directly. The individuals are hired by firms in competitive labor markets, and are paid money wages,  $M_1, \dots, M_N$ , that are based on the firms' estimates of their ability levels. Suppose, in particular, that

$$(11) \quad M_i = z\hat{A}_i + (1-z)A_i, \quad i=1, \dots, N,$$

where  $0 < z < 1$ , and  $\hat{A}_i$  is the best estimate (in a sense to be defined presently) of indi-

vidual  $i$ 's ability that is available to persons outside the firm. That is to say, let us suppose that the wage a worker ultimately receives from the firm he works for is an unbiased amalgam of his true marginal product,  $A_i$ , and the best estimate thereof that was available to the firm when the worker was a job applicant. How job applicants look on paper may be of interest in its own right to employers (especially for jobs in which contact with people outside the firm is important), or may influence the extent to which firms invest in subsequent training for applicants.

Suppose that consumption of observable goods  $x_i$  is related to income  $M_i$  according to

$$(12) \quad x_i = g(M_i) + \gamma_i, \quad i=1, \dots, N,$$

where  $\gamma_i$  is a random term with  $E(\gamma_i) = 0$  and  $\text{var}(\gamma_i) = \sigma_\gamma^2$ . Faced only with information on  $x_i$ , an outside observer who knows the parameters that characterize the deterministic component on the right-hand side of equation (12) then has available an unbiased estimate of  $M_i$ , in the form of

$$(13) \quad \hat{M}_i = g^{-1}(x_i),$$

where  $g^{-1}(\cdot)$  denotes the inverse of the function  $g$ . Writing  $g = \beta(M_i) \cdot M_i = \beta_i M_i$ , and noting from equation (11) that the expectation of  $M_i$  equals  $A_i$ , the outside observer thus has an unbiased estimator of  $A_i$ , conditional on  $x_i$ , call it

$$(14) \quad \hat{A}_i^1 = x_i / \beta_i.$$

Now suppose the outside observer also has some other independent information about  $A_i$ . In particular, suppose there is a test  $T_i$  that satisfies

$$(15) \quad T_i = A_i + \tau_i, \quad i=1, \dots, N,$$

where  $\tau_i$  is a random term with  $E(\tau_i) = 0$  and  $\text{var}(\tau_i) = \sigma_\tau^2$ , for all  $i$ . The information in this test and the information about  $A_i$  from equation (14) can then be melded to form a composite estimate of  $A_i$ . From the

<sup>8</sup>Spence (ch. 8) attributes to Richard Zeckhauser the idea that consumption may act as a signal of ability.

stochastic independence of  $\tau_i$  and  $\gamma_i$ , it follows that the weighted sum

$$(16) \quad \hat{A}_i = \frac{\beta_i^2(1-z)\sigma_\tau^2}{\beta_i^2(1-z)\sigma_\tau^2 + \sigma_\gamma^2} \frac{x_i}{\beta_i} + \frac{\sigma_\gamma^2}{\beta_i^2(1-z)\sigma_\tau^2 + \sigma_\gamma^2} T_i,$$

is the minimum variance unbiased estimator for  $A_i$  in the class of linear combinations of  $T_i$  and  $x_i/\beta_i$ .

Given the ability estimate in equation (16), any individual can increase outsiders' estimates of his ability by devoting more of his resources to the purchase of  $x$ , according to

$$(17) \quad \frac{d\hat{A}_i}{dx_i} = \frac{\beta_i(1-z)\sigma_\tau^2}{\beta_i^2(1-z)\sigma_\tau^2 + \sigma_\gamma^2}.$$

The strength of this effect increases with the budget share for observables,  $\beta_i$ , and with the test variance,  $\sigma_\tau^2$ , and is inversely related to  $\sigma_\gamma^2$  and  $z$ . Unless the budget share for observables is very small, or the independent ability test extremely accurate, any one individual may substantially enhance others' estimates of his ability by increasing the share of his budget devoted to observables. For the particular case of  $z=1/2$ ,  $\beta_i=.8$ , and  $\sigma_\tau^2=\sigma_\gamma^2$ , the elasticity of  $\hat{A}_i$  with respect to  $x_i$  is more than .24, a very substantial effect indeed. Even when the effect on ability estimates of increasing  $x$  is much smaller than in the above example, it may nonetheless be sufficient to alter the outcome of important decisions regarding closely ranked candidates. Close employment decisions, for example, can obviously be influenced decisively even by very weak correlates of ability: placement counselors have long stressed the importance of quality attire and a good address in the job-search process.

To the extent that important outcomes do indeed hinge on the signals implicit in observable consumption levels, individuals who do not rearrange their consumption bundles in favor of observable goods will not always fare better than those who do. It may even

be the case that curtailing the *proportion* of income devoted to unobservable consumption goods will enhance an individual's earnings to such a degree as to raise the actual *level* of consumption of unobservables. Thus, while reduced consumption in the current period is normally thought of as enhancing consumption possibilities in later periods, precisely the opposite result may obtain if current consumption is an important indicator of ability. First impressions often count for a lot, and as the apparel companies are fond of reminding us, one doesn't get a second chance to make a first impression.

But while devoting extra resources to the consumption of observables may be highly adaptive from the point of view of the individual, it is clearly suboptimal from the point of view of the population as a whole. One individual's forward move in any hierarchy can occur only at the expense of backward moves by others. If some individuals rearrange their consumption bundles to favor observable goods, others who do not do so will then be perceived as standing lower in the distribution of productive ability than they actually do. One individual's "offensive" signal is cancelled by another's "defensive" signal, and in the end too many resources are devoted to the consumption of observable goods.

The ability-signaling rationale for imitative behavior suggests that incentives to distort consumption in favor of observable goods will be inversely related to the amount and reliability of independent information that exists concerning individual abilities. Stable environments in which long-standing social networks exist will have more such information than do less-stable environments, and for this reason the budget shares of unobservables should be larger in the former than in the latter. In the same vein, people who move frequently should have lower budget shares for unobservables than those who stay put.<sup>9</sup> To the extent that in-

<sup>9</sup>These observations are in accord with, and suggest a possible basis for, the fact that consumption patterns in small towns are often said to exhibit a certain sanity that metropolitan consumption patterns seem to lack.

dependent measures of an individual's ability become more numerous and reliable as an individual grows older, we expect budget shares for observables to decline with age. To the extent that individuals are in competition with one another for potential mates, budget shares for unobservables should be higher for married persons than for unmarried persons.<sup>10</sup>

Whether these predictions of the ability-signaling model will find empirical support remains to be seen. But even if imitative behavior could not be easily rationalized on the basis of the characterization of individual self-interest offered here, there would remain the question of whether the predictions about spending behavior made in Sections I and II are empirically valid. To this question let us now turn.

#### IV. A Survey of Empirical Evidence

##### A. *Savings vs. Income*

For many years economists struggled to resolve the apparent paradox implicit in the observation that the average propensity to consume falls with income in cross-section data, but is constant in time-series data. Duesenberry's proposed solution to this puzzle in 1949 was essentially the same as the one stated in Proposition 3' above, namely, that demonstration effects weigh relatively

more heavily on people with lower incomes, causing them to consume higher fractions of their incomes than do people with higher incomes. This sense of relative deprivation is not attenuated by across-the-board changes in absolute income, and Duesenberry thus saw no reason for aggregate income growth to alter the average propensity to consume over time.

Though Duesenberry's explanation was persuasive to many, and seemed an intuitively plausible description of how people actually behave, it is fair to say that many economists felt uncomfortable with what they regarded as a sociological theory of the consumption function. To many economists, the notion of consumers being strongly influenced by demonstration effects in consumption must have seemed troublingly at odds with the postulate of rational pursuit of self-interest. It is hardly surprising, therefore, that the profession later so warmly embraced Milton Friedman's permanent income hypothesis (1957) and the life cycle hypothesis of Franco Modigliani and Richard Brumberg (1955). Without relying on vague constructs borrowed from other branches of the social sciences, these theories provided clear a priori reasons, carefully grounded in utility-maximizing behavior, for the observed pattern of average propensities to consume in time-series and in cross-section data.

There is no question that the phenomena addressed by the permanent income and life cycle theories are real and important. But these theories simply cannot account fully for the positive relationship between savings rates and incomes we observe in cross-section samples of individuals. The life cycle and permanent income theories of saving both insist that if the influence of life cycle differences and transitory earnings could be eliminated, we would then see that high-income persons save the same fractions of their incomes as do low-income persons. In study after careful study, however, this prediction has failed to find empirical support. Thomas Mayer (1966), for example, has argued that one way of eliminating the effects of transitory earnings variations is to look at average savings rates across occupations. Though in any given year, for example, some

---

Differences between urban and rural consumption patterns may thus spring less from fundamental differences in the personal values held by the two groups than from differences in the payoffs they face from consuming observable goods.

<sup>10</sup> The importance of sending ability signals via the goods one consumes will naturally vary with one's chosen occupation. Earnings and the abilities that count most among research professors are not very strongly correlated, and many professors think nothing of continuing to drive a 10-year-old automobile if it still serves them reliably. But only in a very small town, where people know one another very well, might it not be a mistake for an aspiring young attorney to drive such a car in the presence of his potential clients. Good lawyers generally earn a lot of money, and people with a lot of money generally drive fashionable new cars. The potential client who doesn't know better is likely to assume that a lawyer with a battered car is not much sought after.

attorneys will have higher incomes than normal, others will have unusually low incomes; in a large sample of attorneys, therefore, the surpluses of those who had good years will largely cancel the shortfalls of those who had bad years. Mayer observed that the permanent income hypothesis requires that the average savings rate for an occupation should thus be independent of its average income level. He then gathered data on average savings rates and average income levels for different occupations in numerous Western countries during different periods in the twentieth century. For virtually every country for which the necessary data were available, Mayer found occupational savings rates positively correlated with average income levels by occupation, a pattern that is flatly inconsistent with the permanent income hypothesis.<sup>11</sup>

H. W. Watts (1958) went a step further by studying the savings behavior of groups of individuals selected so as to represent similar heterogeneous cross sections of the population with respect to age. In so doing, Watts eliminated not only transitory earnings effects by focusing on group averages, but life cycle effects as well. He notes that it is clear from his findings that other factors besides income affect savings rates, but that it is equally clear that there is a significant positive relationship between savings rates and lifetime income.

Perhaps the most damaging evidence against the life cycle and permanent income theories has come in a recent study by Peter Diamond and J. A. Hausman (1982). Using data that record the spending and savings behavior of the same group of individuals

over a multiyear period, Diamond and Hausman find that, even after accounting for permanent income and life cycle effects, savings rates still rise substantially with incomes. They write

...[O]ur most important finding is the extent to which the savings to permanent income ratio rises with permanent income. Not only does the level of savings (wealth) rise with permanent income, but it does so in a sharply non-linear fashion.... [for permanent incomes below \$4770 per year, the savings-permanent income ratio rises by 3.3 percent for each extra \$1000 of permanent income;] beyond \$4700 it rises 5.7% for each extra \$1000 and beyond \$12,076 it rises by 14.2%. These results strongly confirm... that a simple linear relationship between savings and permanent income is not supported in our data. ... [pp. 36-37]

Numerous other authors have presented evidence that savings rates are positively related to life cycle and permanent income.<sup>12</sup> In his review of this evidence, Mayer wrote, "...of all the many tests which have been undertaken by friends of the [proportional savings rate] hypothesis, *not a single one supports it*... I therefore conclude that the proportionality hypothesis is definitely invalidated..." (1972, p. 348).

The evidence on the savings vs. income relationship is so strong and so consistent that it would appear difficult for proponents of the permanent income and life cycle theories to continue to insist that savings rates are unrelated to income. Yet these claims persist in most major undergraduate and graduate texts in macroeconomics.<sup>13</sup>

I have argued here that, in contrast to the permanent income and life cycle theories, a consumption theory that incorporates people's concerns about relative standing is able

<sup>11</sup>Some authors (see, for example, P. L. Menchik, 1979) have attempted to reconcile the life cycle and permanent income hypotheses to the savings rate data by arguing that the rich are motivated to bequeath larger shares of their lifetime wealth to their heirs than are the poor. Yet the aggregate ratio of bequests to national income has not risen hand in hand with income as a consumption theory based on absolute wealth would require. If, on the other hand, the bequest motive depends on relative wealth, then the permanent income and life cycle theories are almost indistinguishable from Duesenberry's relative income theory.

<sup>12</sup>For a thoughtful survey of these studies, see Mayer (1972).

<sup>13</sup>At least two leading macroeconomics texts (Thomas Sargent, 1979, and Robert Gordon, 1978) do not even mention the relative income hypothesis at all.

to account for the observed positive relationship between savings rates and income. Granted, the permanent income and life cycle theories have made an important contribution to our understanding of consumer behavior—long-run considerations *are* important to most consumers, and anyone who ignores that fact will make systematic errors when trying to predict consumer behavior. But in view of the empirical evidence, the extent to which these theories have supplanted Duesenberry's relative income hypothesis in modern textbooks seems yet another testament to the power of the *a priori* beliefs held by most economists. This outcome is not without irony, since we have seen that concerns about relative standing may well be fully compatible with the rational pursuit of self-interest, and therefore presumably not at all in conflict with economists' important prior beliefs. If this view wins acceptance, it suggests that greater attention be accorded to Duesenberry's explanation of the savings rate paradox, at least until some new empirical evidence is uncovered that proves it faulty.<sup>14</sup>

### B. *Union vs. Nonunion Compensation Packages*

To examine Proposition 1 requires that we uncover some source of variation in the extent to which individuals are able to form cooperative consumption agreements with other members of their personal reference groups (the "relevant population" noted in Section II). Both union and nonunion firms commonly facilitate collective consumption agreements regarding insurance, savings, and a variety of other fringe items. Several considerations suggest, however, that union

members are relatively better positioned to implement such agreements than are their nonunion counterparts. First, the average length of job tenure is much higher for union than for nonunion members,<sup>15</sup> which presumably will give rise to closer personal associations between coworkers in union firms than in nonunion firms. Accordingly, a union member's personal reference group should be more heavily composed of coworkers than should the nonunion worker's. Second, a similar tendency should emerge as a result of union firms being larger, on average, than nonunion firms. Third, the very existence of the union's administrative apparatus may facilitate an exchange of information between coworkers that enhances the likelihood of their being able to form agreements about how compensation should be allocated between various budget categories.<sup>16</sup> These considerations suggest that budget shares devoted to nonpositional goods should be higher for union members than for nonunion members.

The sociological literature on reference group theory stresses that an individual's personal reference group tends to consist disproportionately of others who are similar in terms of age, education, and various other background variables.<sup>17</sup> We also know that union members earn significantly higher wages than do nonunion workers with comparable job skills.<sup>18</sup> These observations together imply that a union member with a given income level will have higher income relative to the noncoworkers in his personal reference group than will a nonunion worker with the same nominal level. Referring to Proposition 3, this union-nonunion difference in rank *vis-à-vis* noncoworker refer-

<sup>14</sup>Robert Clower was thus, in my view, correct when he wrote that "...there seems to be no reason why the basic Duesenberry ideas should not be accepted as an integral part of the pure theory of consumer behavior" (1952, p. 178.) But he went on to say "...one gets the impression... that the interdependence postulate is comparatively innocuous as concerns established doctrines; but this remark may require considerable qualifications in the light of subsequent, and perhaps more sophisticated, inquiries" (p. 178). This inquiry is hardly a very sophisticated one, but it does suggest a number of such qualifications.

<sup>15</sup>Jacob Mincer (1983) finds, for example, that quit rates in the union sector are about one-half as large as in the nonunion sector for young men and about one-third as large for men over 30.

<sup>16</sup>See, for example, the arguments advanced by Albert Hirschman (1970).

<sup>17</sup>See, for example, Robert Merton and Alice Kitt (1950), Leon Festinger (1954), James Davis (1959), and Robin Williams (1975).

<sup>18</sup>Mincer (1983), for example, finds ability-adjusted union wage premiums of 6–14 percent for men under 30, and 4–12 percent for older men.

ence group members will act to reinforce the specific predictions about union-nonunion differences in the shares of total compensation devoted to nonpositional goods.

Richard Freeman (1981) has examined the effect of collective bargaining on the fringe share of the compensation package, and his findings are strongly in accord with Proposition 1. Using data from the Bureau of Labor Statistics' *Expenditures for Employee Compensation Survey*, Freeman estimated the effect of collective bargaining on eight components of voluntary fringe benefits. These results are reproduced here as Table 2. The coefficients reported therein represent partial effects of unionism on the various fringe items, wage income having been included as an explanatory variable in the regression equation from which those coefficients were taken. Given what intuition tells us about what constitutes a positional consumption good, the coefficients in Table 2 are strikingly consistent with the hypothesized effect of unionism on the structure of compensation.

Note, for example, that collective bargaining has its largest impact on fringe items 1 and 4. Union workers devote almost 48 percent more to insurance benefits than do nonunion workers with the same income levels. Similarly, union workers devote more than 41 percent more to pensions than do nonunion workers with the same income levels. These findings are in strong accord with the hypothesis that cooperative decisions will tend to favor unobservable goods. The finding that union workers devote a larger share of total compensation to "paid" vacations than do similarly situated nonunion workers is consistent with the view that leisure is a nonpositional good.

Freeman's estimates of the effects of collective bargaining on shift differentials and overtime premiums offer a mixed message for the theory of collective bargaining offered here. That union members have higher shift differentials (for example, premiums for working at night) is consistent with the notion that union workers will act more effectively than others do to limit the extent to which they exchange unfavorable working conditions for higher incomes. Freeman re-

TABLE 2—THE EFFECT OF COLLECTIVE BARGAINING ON SPECIFIC FRINGES, ALL PRIVATE INDUSTRY, 1967–72

Fringe	Cents per Hour Spent on Fringe	
	(1)	Coefficients <sup>a</sup> (2)
1. Life, Accident, and Health Insurance	10.1	4.8 (0.2)
2. Vacation	8.3	1.6 (0.2)
3. Overtime Premiums	10.1	-0.5 (0.4)
4. Pension	9.4	3.9 (0.4)
5. Holidays	5.2	0.8 (0.1)
6. Shift Differential	1.1	0.3 (0.1)
7. Sick Leave	1.1	-0.5 (0.1)
8. Bonuses	1.8	-1.4 (0.3)

Source: Freeman (1981, Table 4, p. 503).

<sup>a</sup>For the effect of collective bargaining on col. 1. Standard errors are shown in parentheses.

ports, however, that overtime premiums are actually smaller for union workers than for nonunion workers. That finding does not support the view of union objectives offered here. But the union-nonunion difference is less than 5 percent of the total devoted to this fringe item, and is not statistically significantly different from zero. Overtime premiums, moreover, are largely dictated to employers by the provisions of the Fair Labor Standards Act, so it is not clear that we would expect to see significant union-nonunion differences in this item in any event. Sick leave is also smaller for union than for nonunion workers, though the difference here too is small.

Note, finally, that Bonuses (item 8) are substantially smaller for union workers than for nonunion workers with the same incomes. Bonuses are equivalent to wage income insofar as both come in the form of cash. Bonuses therefore represent a portion of the compensation package that is left free from any collective allocation pattern the respective groups may wish to promote. Accordingly, Proposition 1 predicts that the bonus item will be larger for nonunion than

for union workers who have similar income levels. And Freeman does find the former to be four and one-half times the latter.

Needless to say, other explanations than the one advanced here may be offered in support of the coefficient pattern we see in Table 2. Freeman's own explanation for the observed difference in fringe shares relies on the assumption that older workers are simultaneously less mobile and have greater demands for fringe benefits than do younger, less tenured workers. He asserts that the demands of more senior workers are effectively expressed through the collective bargaining mechanism, but tend to be understated in the competitive outcome, where the compensation package is shaped primarily by the preferences of younger, more mobile workers, who are relatively less concerned about fringe benefits. Let us briefly consider this alternative explanation.

Freeman's explanation requires that non-union employers, who are assumed to employ captive older workers, be unable to design a discriminatory compensation package that simultaneously appeals to the tastes of both junior and senior employees alike. If employers are free, as they appear to be, to offer compensation packages in which both wages and fringes can be linked by formula to the employee's length of tenure with the firm, then Freeman's nonunion firm must have higher labor costs than (and should eventually be driven out by) other nonunion firms that pay lower wages but provide greater fringe benefits to more senior workers. Indeed, union and nonunion establishments alike do in practice link both wage payments and at least some fringes, such as pensions and vacations, directly to length of tenure with the firm. Other fringes, such as life and accident insurance, are often linked to total compensation, which, in turn, is highly correlated with tenure. Just as Freeman's argument implies non-cost-minimizing behavior on the part of nonunion firms, it also requires non-utility-maximizing behavior on the part of unions. Since fringe packages are easily designed to discriminate by age, why should older union workers force younger workers to consume uneconomically large shares of compensation in the form of fringe benefits?

Mincer (1984) finds a pattern of union-nonunion compensation differences similar to the one found by Freeman, for which he offers yet another explanation. Mincer argues that union workers are fearful that if they raise wages too high, firms will find it profitable to constrain the number of hours employees may work. Mincer doesn't say, but the reason that unions don't simultaneously bargain with firms to prevent such hours reductions is perhaps that unpredictable variations in product demand (unobservable by workers) make it inefficient to do so. In any event, Mincer then argues that union workers try to frustrate this stratagem by demanding a larger share of their compensation in the form of fringe benefits, which act as lump sums in the compensation schedule, thus reducing the marginal gain to firms of curtailing hours worked.

This is a curious strategy for a union to pursue. Any union that had sufficient bargaining power to implement such a strategy presumably would also have sufficient power to demand and get a cash intercept term appended to its weekly salary formula. Shifting part of cash compensation into such an intercept term would produce the same change in marginal conditions facing firms as would shifting compensation into lumpy fringe benefits, but would afford workers greater latitude in their consumption decisions, and would lead therefore to higher utility levels for union workers.

Arguments similar to the ones discussed above may be applied to the comparison of safety levels across union and nonunion firms. Elsewhere (1985, ch. 7) I have argued that consumption decisions regarding "contingent goods" have many of the same properties as those that apply to nonpositional goods. A contingent good is one that has a payoff only if some unlikely event occurs. Insurance and safety devices are examples of such goods. If contingent goods are like nonpositional goods, then union workers should devote larger shares of total compensation to safety than should otherwise similar non-union workers.

Unfortunately, little reliable information exists on the total level of expenditures firms make to promote health and safety in the

workplace. But if union workers are better able to express cooperative demands for safety than are nonunion workers, it then follows that (holding income and the level of risk exposure constant) the reservation price for accepting a given increment in risk exposure should be higher for union than for nonunion workers.

In their widely cited 1976 paper, Richard Thaler and Sherwin Rosen report the results of a statistical study whose structure is well-suited for testing this hypothesis. In their study, they estimate that the union worker must receive a risk premium that is \$8.08 per week higher than the premium required by an identically situated nonunion worker for accepting a 1/1000 increase in the annual probability of death. The particular estimate of interest from the Thaler-Rosen study is their regression coefficient for the interactive effect of risk and union membership. A test of the null hypothesis that collective bargaining does not affect the wage-risk tradeoff translates in the Thaler-Rosen study as a test of the hypothesis that the coefficient on the (risk  $\times$  union) variable is zero. The *t*-statistic for this coefficient is 2.02, which enables us to reject the null hypothesis at conventional significance levels. The union-nonunion difference in risk premiums amounts to a substantial fraction (often more than one-half) of the total risk premium workers receive in return for the performance of risky tasks.<sup>19</sup>

W. Kip Viscusi (1980) has constructed an alternative explanation for higher union safety levels by arguing that union and nonunion workers have the same preferences over safety and wage income, but weigh the preferences of older, more risk-averse employees differently during the bargaining process. This explanation is identical in its structure to Freeman's explanation of why the fringe share of the compensation package is higher for union than for nonunion workers. And it suffers, therefore, from many of the same difficulties. In most firms there is a menu of different tasks to be performed,

and not all these tasks are equally risky. Under such circumstances, the preferences of risk-averse older workers can be accommodated by simply assigning younger workers to the relatively more risky tasks. That firms do not do so suggests that some factor other than age-related differences in preferences must explain the difference in safety levels between union and nonunion firms.<sup>20</sup>

The foregoing differences in the ways union and nonunion workers allocate their total compensation suggest an alternative interpretation of the role of the trade union movement. Many accounts of the trade union movement have stressed the role of unions as a force for neutralizing excessive market power in the hands of firms.<sup>21</sup> But if concerns about relative standing are as strong as they appear to be, the presence of monopsony power is not logically necessary to explain why individual workers might sell various aspects of their services too cheaply. When relative standing is important, there are sensible reasons, quite apart from the prospect of an increase in total compensation, why workers might seek to determine the distribution of compensation collectively rather than individually.

## V. Concluding Remarks

The interdependent choice framework discussed here suggests alternative interpretations of a variety of apparently paternalistic laws and regulations. The Social Security program, for example, has been defended on the grounds that consumers lack sufficient

<sup>19</sup>For a thoughtful survey of the literature on compensating wage differentials for exposure to risk, see Robert Smith (1979).

<sup>20</sup>Perhaps the older workers are behaving paternalistically (and altruistically, too, since it costs them money) toward the younger union workers. But altruism cannot account for the parallel implications of Viscusi's argument for behavior in nonunion firms. For why would nonunion firms inflict uneconomically large risk burdens on risk-averse older workers? In Viscusi's framework, both the firm and the older worker could do better by shifting the older workers from risky to less-risky tasks.

<sup>21</sup>For a completely unequivocal statement of this view, see John Mitchell (1903). More recent accounts paint a much broader picture of what trade unions do, but their role as a countervailing force to the market power of firms continues to be emphasized (as, for example, in the Viscusi and Freeman papers cited above).

foresight and self-discipline to save effectively for their retirement. But we have seen that such forced savings programs might have a coherent role to play even in a world populated by rigidly disciplined consumers with perfect foresight. The problem of inadequate savings arose here not because of character defects, but because of a divergence between individual and collective incentives to save.

Overtime laws, health and safety regulations, and a variety of other restrictions of competitive labor contracts have similarly been explained as devices needed to protect workers from being ravaged by avaricious monopsonists. The interdependent choice framework discussed here suggests the possibility of a useful role for those same institutions even in perfectly informed, atomistically competitive labor markets.

Now, it is easy to imagine the line of discussion pursued here being used to justify a host of egregiously meddlesome regulatory activities. Yet such a regulatory response would hardly be in keeping with the traditional remedies economists have proposed for problems that arise from the presence of externalities. If consumption externalities do indeed motivate many of the command-and-control regulatory interventions we currently observe, then a simple tax on positional consumption expenditures might attenuate the need for many of these interventions. If consumption externalities are as important as they appear to be, then supply sides have got matters turned completely around when they insist that income and consumption taxes introduce serious distortions into the labor-leisure choice. When relative standing is important, such taxes serve, on the contrary, to mitigate an already present distortion in that choice.

# Fiscal Policy and Aggregate Demand

By DAVID ALAN ASCHAUER\*

This paper is an investigation of the effects of fiscal policy on private consumption and aggregate demand within an explicit intertemporal optimization framework. Empirical evidence is brought to bear on the following questions: Is consumption sensitive to the choice of tax versus debt financing of current government expenditure? To what extent, if any, does government spending directly substitute for private consumer expenditure?

The first question has stimulated a considerable amount of research since Robert Barro's (1974) revival of the "Ricardian equivalence" proposition. Lewis Kochin (1974), Barro (1978), J. Ernest Tanner (1979), and Roger Kormendi (1983) obtain empirical results favorable to the proposition that, to a first approximation, the choice between current taxation and debt issuance to finance a given government expenditure stream is irrelevant to the determination of the level of aggregate demand. On the other hand, Martin Feldstein rejects some of the assumptions adopted in the empirical specifications of Kochin, Barro, and Tanner, and comes to the conclusion that "... each of the basic implications of the so-called 'Ricardian equivalence theorem' is contradicted by the data" (1982, p. 9).

The second question has also been touched upon in recent empirical studies. Feldstein's (1982) results detract from the proposition of "fiscal neutrality" whereby an increase in government spending induces an *ex ante* crowding out of an equal amount of private consumption expenditure. However, Kormendi obtains support for his "consolidated approach" to fiscal policy by finding a substantial degree of substitutability between

government spending and private consumption.

The argument advanced in this paper is that probable misspecification bias in these previous studies renders the results suspect and may account for the fact that minor changes in the empirical models lead to radically different conclusions regarding the potency of fiscal policy. In place of the conventional methodology, an alternative approach is presented which exploits restrictions placed on the data by the first-order necessary conditions for intertemporal optimization in consumption. The empirical evidence is supportive of the joint hypothesis of rational expectations and Ricardian equivalence as well as of the proposition that government spending substitutes poorly for private consumption in utility.

## I. Effective Consumption and Intertemporal Optimization

Here I develop the model to be estimated later in the paper and point out some inherent difficulties in previous tests of fiscal neutrality. The theory applies to a representative individual who has time-separable preferences over private consumption,  $C$ , and the goods and services flowing from the government sector,  $G$ . Specifically, the agent's utility function is given by

$$(1) \quad V_t = \sum_{j=0}^{\infty} (1/(1+\delta))^j u(C_{t+j}^*),$$

where  $\delta$  is a constant rate of time preference and  $u(\cdot)$  is a time-invariant, concave momentary utility function. Finally,  $C_t^* = C_t + \theta G_t$  denotes the level of "effective" consumption in period  $t$ , a linear combination of private consumption and government goods and services. The constant marginal rate of substitution implies that a unit of govern-

\*Department of Economics, University of Michigan, Ann Arbor, MI 48109. I thank Robert King and members of the University of Michigan Money Seminar for useful comments. Any errors are my responsibility.

ment goods and services yields the same utility as  $\theta$  units of private consumption.<sup>1</sup>

The representative agent is allowed unrestricted access to a capital market at which he may accumulate or decumulate assets at the assumed constant real rate of interest  $r$ . His period  $t$  flow budget constraint is given by

$$(2) \quad W_{t+1}/(1+r) - W_t + C_t = N_t - T_t$$

where  $W_t$  = beginning of period holdings of one period bonds (which includes government debt), each unit of which is a claim to a unit of output,  $N_t$  = period  $t$  labor earnings and  $T_t$  = period  $t$  tax payments (net of transfers). Forward substitution in equation (2) yields

$$(3) \quad \sum_{j=0}^{\infty} (1/(1+r))^j C_{t+j} \\ = W_t + \sum_{j=0}^{\infty} (1/(1+r))^j [N_{t+j} - T_{t+j}],$$

which equates the present discounted value of private consumption expenditure to initial asset holdings plus the present discounted value of net of tax labor earnings.<sup>2</sup>

The government sector has a flow budget constraint of the form

$$(4) \quad B_{t+1}/(1+r) - B_t + T_t = G_t,$$

where  $B_t$  = government debt of one-period maturity. Provided that the government debt grows at a rate less than the real rate of return,<sup>3</sup> equation (4) may be utilized to pro-

duce

$$(5) \quad \sum_{j=0}^{\infty} (1/(1+r))^j T_{t+j} \\ = B_t + \sum_{j=0}^{\infty} (1/(1+r))^j G_{t+j}$$

which equates the present discounted value of tax receipts to the initial government debt plus the present discounted value of government purchases.

The representative individual is assumed to be "forward looking" in regard to the fiscal affairs of the government. In particular, the agent recognizes the future tax obligations implicit in current debt issuance, which allows an equivalence between tax or debt finance of a given government expenditure stream. In addition, the individual takes into consideration the benefits to be derived from the future provision of goods and services by the government. Accordingly, the private and public sectors can be integrated by the substitution of the government budget constraint (5) into the representative agent's budget constraint (3) to obtain the following budget constraint in terms of effective consumption:

$$(6) \quad \sum_{j=0}^{\infty} (1/(1+r))^j C_{t+j}^* = (W_t - B_t) \\ + \sum_{j=0}^{\infty} (1/(1+r))^j [N_{t+j} + (\theta - 1)G_{t+j}].$$

Thus, the present discounted value of effective consumption is constrained by the level of net economywide wealth ( $W_t - B_t$ ), plus the present discounted value of labor earnings, plus  $(\theta - 1)$  times the present discounted value of government expenditure. The last term arises because a higher level of government spending imposes a negative (positive) wealth effect on the representative individual as long as  $\theta < (>) 1$ .

The maximization of the individual's objective function (1) subject to the effective intertemporal budget constraint (6) yields as

<sup>1</sup>See, for example, Barro (1981). I ignore other possible channels of influence of government spending on the economy such as providing infrastructure capital as an input to private production processes. On related matters, see my earlier paper (1983) and Willem Buiter (1977).

<sup>2</sup>The solvency condition  $\lim_{k \rightarrow \infty} (1/(1+r))^k w_{t+k} = 0$  has been imposed to obtain equation (3).

<sup>3</sup>To be exact, I impose  $\lim_{k \rightarrow \infty} (1/(1+r))^k B_{t+k} = 0$ . The conditions under which this is likely to hold are discussed by Barro (1974, 1976) and Feldstein (1976).

first-order necessary conditions

$$u'(C_{t+j}^*) = \lambda \cdot ((1+\delta)/(1+r))^j$$

$$j = 0, 1, 2, \dots,$$

along with the intertemporal budget constraint (6). Here,  $\lambda$  is a Lagrangian multiplier attached to (6) in the consumer's maximization problem. The consideration of the choice of consumption in the adjacent periods  $t$ ,  $t+1$  then leads to the Euler equation

$$(7) \quad u'(C_{t+j}^*) = [(1+\delta)/(1+r)]^j u'(C_t^*).$$

Hence, in order for the individual to be choosing an optimal (interior) time path for effective consumption, it must be the case that he cannot improve his welfare standing by reducing effective consumption in one period, say  $t$ , and increasing effective consumption during another period, say  $t+1$ . The cost of reducing effective consumption during period  $t$  and purchasing a bond would be the reduction in utility such an action would entail, or  $u'(C_t^*)/(1+r)$ . The benefit of this action would be the (subjectively discounted) gain in utility during period  $t+1$  to be obtained from the proceeds of the investment, which would be  $u'(C_{t+1}^*)/(1+\delta)$ .

Note the generality of condition (7). For instance, this condition should hold even if utility were also dependent upon leisure (in a manner separable from effective consumption) and there were quantity constraints in the labor market. As long as free access to the credit market is allowed, the agent would allocate resources so as to attain a smooth consumption profile even if during certain periods of his life he faced a situation of involuntary unemployment.

In order to obtain a closed-form solution for consumption, the form of preferences is restricted in the objective function (1). Assuming the momentary utility function is quadratic so

$$u(C_t^*) = -(\bar{C}^* - C_t^*)^2/2,$$

where  $\bar{C}^*$  is the bliss level of effective con-

sumption, the Euler equation is given by

$$(8) \quad C_{t+1}^* = \alpha + \beta C_t^*,$$

where  $\alpha \equiv [(r-\delta)/(1+r)]\bar{C}^*$  and  $\beta \equiv (1+\delta)/(1+r)$ . Using (8) to substitute out  $C_{t+j}^*$  ( $j=1, 2, \dots$ ) and equation (6) allows us to write

$$(9) \quad C_t^* = [(\delta-r)/r(1+r)^2]\bar{C}^* + \left[ \frac{r^2+2r-\delta}{(1+r)^2} \right] \left\{ \sum_{j=0}^{\infty} \left( \frac{1}{1+r} \right)^j [N_{t+j} + (\theta-1)G_{t+j}] + (W_t - B_t) \right\}.$$

Finally, the separation of the period  $t$  levels of income and government spending from the present value term in (9) yields the specification

$$(10) \quad C_t = \beta_0 + \beta_1 N_t + \beta_2 W_t + \beta_3 G_t + \beta_4 T_t + \beta_5 B_t + \beta_6 \sum_{j=1}^{\infty} \left( \frac{1}{1+r} \right)^j N_{t+j} + \beta_7 \sum_{j=1}^{\infty} \left( \frac{1}{1+r} \right)^j G_{t+j},$$

where  $\beta_0 = (\delta-r)\bar{C}^*/[r(1+r)^2]$ ,  $\beta_1 = \beta_2 = -\beta_5 = \beta_6 = \beta_7/(\theta-1) \approx r/(1+r)$ ,  $\beta_3 \approx -(r+\theta)/1+r$ , where the approximations are for  $\delta \approx r$ , and  $\beta_4 = 0$ .

Let us consider the relationship between the specification in equation (10) and that to be found in Feldstein's previous study (1982) of fiscal policy effectiveness:<sup>4</sup>

$$(10') \quad C_t = b_0 + b_1 Y_t + b_2 W_t + b_3 G_t + b_4 T_t + b_5 B_t,$$

<sup>4</sup>I abstract from Social Security wealth although it could be readily incorporated into the analysis. Also, it should be noted that similar criticisms could be made of other studies using the same methodology. Feldstein's was chosen at random.

where all variables are as measured before and  $Y_t$  is permanent income, measured by total national income. Feldstein argues, first, that the Ricardian equivalence theorem implies the restrictions  $b_4 = 0$  and  $b_2 + b_5 = 0$ , which are in accord with the theoretical coefficients in equation (10). Second, he asserts correctly that a test of full fiscal neutrality, whereby current changes in government spending induce an equal, opposite shift in private consumption, would entail the additional restriction that  $b_3 = -1$  in equation (10'). Despite the fact that the proposed restrictions are correct for the test of the null hypothesis, at least three criticisms can be pointed toward this formulation.

The first obvious criticism arises from the treatment of current income as exogenous for the purpose of estimation. As first pointed out by Trygve Haavelmo (1943), since the disturbance term will not be orthogonal to current income, biased and inconsistent estimates will arise in ordinary least squares regression. Feldstein attempts to correct for this bias by employing instrumental variables for income and taxes in some of the reported regressions. Still, the chosen instruments—lagged income and taxes—may not be able to fully eliminate the bias due to serial correlation in the data series. (See Feldstein, 1982, p. 13.)

Second, in his empirical work, Feldstein enters a lagged value of total national income to capture any extra information it may contain as to permanent income. Implicit is the assertion that national income follows a second-order autoregressive process. In this context, it would seem more appropriate to follow Thomas Sargent (1978) by postulating an auxiliary equation for income and computing estimates subject to the cross-equation restrictions between the stochastic processes governing consumption and income which would be imposed by the assumption of rational expectations. Further, the permanent income measure chosen by Feldstein—national income—is inappropriate since it includes future nonlabor income as well as future labor income and the former is already accounted for in the wealth

variable.<sup>5</sup> The appropriate income variable to be chosen is labor income as should be clear from inspection of the specification in (10).

Third, and most important to the issues of the present paper, the formulation in (10') omits any influence of future levels of government spending on current consumption decisions. Feldstein's own fiscal expectations view holds that a change in the current value of government spending or taxes signals future changes in one or both of these variables. This implies that the omitted government spending variables should be expected to be highly correlated with the fiscal policy variables which are included in (10'). Consequently, the coefficient estimates of the latter variables will be biased and will result in incorrect inferences regarding the ability of fiscal policy actions to alter aggregate demand. For example, suppose that current tax revenues are positively correlated with future government spending. Then, since the theory predicts consumption to be negatively related to government spending (assuming

<sup>5</sup>As an illustration of this point, suppose wealth is kept fixed at the value  $W_t$  for  $j = 0, 1, \dots$ , so

$$W_t = \sum_{j=0}^{\infty} (1/(1+r))^j R W_t,$$

where  $R W_t \equiv r W_t / (1+r)$  is the future nonlabor income the individual would receive in each period. Abstracting from governmental variables to center on the particular issue under consideration, we could write permanent income as

$$R \left[ W_t + \sum_{j=0}^{\infty} (1/(1+r))^j N_{t+j} \right]$$

or, by substituting for  $W_t$  in this expression,

$$R \left[ \sum_{j=0}^{\infty} (1/(1+r))^j Y_{t+j} \right],$$

where  $Y_{t+j} \equiv [N_{t+j} + R W_t]$  may be taken to be national income. Thus, Feldstein is being redundant in defining permanent income in terms of national income and adding an independent wealth variable in (9').

$0 < \theta < 1$ ), the omission of future government spending from the regression equation (10') will tend to bias the estimated coefficient on the current tax variable below zero and provide an apparent refutation of the proposition of Ricardian equivalence. In this case, the current tax variable merely acts as a proxy for higher expected government spending. The general point is that, since the current values of the fiscal policy variables carry information regarding future government spending, it is difficult to determine the extent to which the statistical significance of the fiscal policy variables in (10') uncovers a true structural relationship.

The approach of this paper is to abandon the methodology of earlier studies in this area of research and instead to utilize the restrictions which the Euler equation (7) places on the data as in Robert Hall (1978), Marjorie Flavin (1981), N. G. Mankiw, Julio Rotemberg, and Lawrence Summers (1982), Lars Peter Hansen and Kenneth Singleton (1983), and others.<sup>6</sup> This avoids the problems cited above and yields evidence on the substitutability of government spending for private consumption and on the joint hypothesis of rational expectations and Ricardian equivalence.

## II. The Data and Empirical Results

In the study of intertemporal consumption behavior, it is of vital importance to distinguish between consumption and consumer expenditure. At any point in time, consumption might arise without any act of consumer spending (for example, the enjoyment of programs from a previously acquired television set) as well as consumer expenditure without consumption (for example, the purchase of a lawn mower at a winter sale). Ideally, then, one would like to add to current consumer expenditure a flow of services from previously acquired consumer durables and to

subtract current expenditures on durable goods to obtain an adequate measure of consumption. In this paper, an attempt at the latter adjustment is made by defining consumption to be consumer expenditures on nondurables and services. Notice, however, that this adjustment is crude since many goods included in this category would still have durable characteristics. Further, no attempt at the former adjustment is made due to the arbitrariness and difficulties involved in the imputation of a service flow from the stock of consumer durables. Therefore, as the term is used in the empirical analysis below, consumption is per capita consumer expenditure on nondurables and services measured in constant (1972) dollars. Quarterly data are used throughout the study.

The empirical analysis assumes, again, quadratic utility but now in an explicitly stochastic environment so that the Euler equation may be written as

$$(11) \quad E_t C_{t+1}^* = \alpha + \beta C_t^*,$$

where, as before,  $\alpha \equiv [(r - \delta)/(1 + r)]\bar{C}^*$ ,  $\beta = (1 + \delta)/(1 + r)$  and  $E_t$  is the expectations operator conditional on information available up through period  $t$ .

I begin by neglecting the predicted theoretical effect of government spending on the time path of consumption so that equation (11) reduces to Hall's (1978) condition written here as

$$(11') \quad E_t C_{t+1} = \alpha + \beta C_t.$$

Hall estimates (11') and finds that the data support the implication of the permanent income hypothesis that consumption follows a random walk with drift.<sup>7</sup> As a further check

<sup>6</sup>Another interesting avenue would be to follow the instrumental variable approach as in Fumio Hayashi (1982).

<sup>7</sup>The important implication of Hall's model is that  $E(u_t X_{t-1}) = 0$  where  $X_{t-1}$  is any variable in the information set at time  $t-1$  other than  $C_{t-1}$ . To see this, consider a simple Keynesian model with an investment accelerator as  $C_t = cY_{t-1} + e_t$ ;  $I_t = v(Y_t - Y_{t-1}) + \eta_t$ ;  $Y_t = C_t + I_t$ , where  $e_t$  and  $\eta_t$  are both white noise processes. The reduced-form equation for consumption is  $c_t = \beta C_{t-1} + u'_t$ , where  $\beta = (v - c)/(v - 1)$  so for  $v$  large

on the validity of the permanent income hypothesis, Hall in sequence introduces lagged values of consumption, disposable income, and wealth to see if these variables have any predictive power for current consumption apart from that of one-period-lagged consumption. Although past values of wealth—as measured by stock prices—turn out to be statistically significant in predicting current consumption, Hall comes to the overall positive conclusion that "... there is little reason to doubt the life cycle-permanent income hypothesis" (p. 985).

As the present paper is concerned with the impact fiscal policy actions have on the intertemporal path of consumption, consider the effect of past government deficits on current consumption as in the following regression equation:

$$(12) \quad C_t = \alpha + \beta C_{t-1} + \gamma_1 D_{t-1} + \gamma_2 D_{t-2} \\ + \gamma_3 D_{t-3} + \gamma_4 D_{t-4} + u_t,$$

where  $D_t$  is the per capita net deficit of the total government sector measured in constant (1972) dollars. The results from estimating this equation by ordinary least squares for the sample period 1948:I to 1981:IV are listed in Table 1.

The deficit variable makes a statistically important contribution to the predictive power of the equation, with primary influence arising from the first and second lagged values. The  $F$ -statistic for testing the null hypothesis that the coefficients on the deficit variable are all zero is equal to 4.17, substantially above the 5 percent critical value of 2.44 for (4,130) degrees of freedom. Thus, at least at first blush, it appears that a damaging blow has been inflicted upon the Ricardian equivalence hypothesis and hence also upon the theoretical structure of this paper.

However, it may be argued that the influence of government financial variables on

private consumption may be more apparent than real, due to the fact that past taxes or deficits may help to predict current government spending. In this case, if government spending substitutes for private consumption in utility, then the estimates of  $\gamma_1, \dots, \gamma_4$  would be expected to be significantly different than zero. Rather than providing a refutation of the joint hypothesis, the above results could be logically interpreted as evidence in favor of the joint hypothesis, provided that the cross-equation restrictions imposed by the theory cannot be rejected at conventional levels of significance.

So as to take consideration of this point, decompose effective consumption into its private and public components and write from equation (11) the following equation:

$$(13) \quad C_t = \alpha + \beta C_{t-1} + \theta \theta G_{t-1} - \theta G_t^e + u_t.$$

Here,  $G_t^e$  is the expected level of government purchases for time  $t$  conditional upon all information available to the agent at time  $t-1$ . Government spending is measured empirically by per capita government expenditure on goods and services in constant (1972) dollars.<sup>8</sup>

The auxiliary equation to be employed in the prediction of the current level of government spending is given by

$$(14) \quad G_t = \gamma + \varepsilon(L)G_{t-1} + \omega(L)D_{t-1} + v_t,$$

where  $\varepsilon(L) = \sum_1^n \varepsilon_i L^{i-1}$  and  $\omega(L) = \sum_1^n \omega_j L^{j-1}$ ,  $L$  being the lag operator  $LX_t \equiv X_{t-1}$ , and  $v_t$  satisfies the orthogonality condition  $E(v_t | I_{t-1}) = 0$  ( $I_s$  being the information set available to the agent at time  $s$ ) so that  $v_t$  is serially uncorrelated. Written in this form, it is postulated that, apart from past values of government spending, past values of government financial variables

and  $C \approx 1$ ,  $\beta \approx 1$ . However, in the Keynesian case we find that  $E_t(u'_t X_{t-1}) \neq 0$ . Crucial to this argument, of course, is the assumption of time separability in the specification of the consumer's preferences.

<sup>8</sup>The empirical analysis does not attempt to differentiate between government purchases which provide current utility and government purchases which provide future utility either directly or indirectly through private production processes. This distinction was made in the later sections of Kormendi.

TABLE 1—ORDINARY LEAST SQUARES ESTIMATE OF EQUATION (12)  
1948:I TO 1981:IV

Constant	$C_{t-1}$	$D_{t-1}$	$D_{t-2}$	$D_{t-3}$	$D_{t-4}$
1.522 (.754)	.99 (.003)	-.054 (.025)	.066 (.036)	-.042 (.036)	-.026 (.025)
$SER = 2.09$ ; $\bar{R}^2 = .998$ ; $h = .875$ ; $F = 4.17$					

Source: Citibank economic database.

Notes: Estimated standard errors are shown in parentheses.  $h$  is Durbin's test statistic for serial correlation in the residuals in the presence of lagged dependent variables.  $F$  is the value of the statistic appropriate for testing the null hypothesis that the coefficients on the lagged values of the government deficit are all zero.  $C_t$  = per capita consumer expenditure on nondurables and services in constant (1972) dollars.  $D_t$  = per capita net deficit of federal, state and local governments in constant (1972) dollars.

summarized by past deficits help to predict current government expenditure. The linear least squares predictor of  $G_t$  is then given by

$$E_{t-1}G_t \equiv G_t^e = \gamma + \varepsilon(L)G_{t-1} + \omega(L)D_{t-1},$$

which, upon substitution into equation (13), yields the two-equation system below:

$$(15a) \quad C_t = \delta + \beta C_{t-1} + \eta(L)G_{t-1} + \mu(L)D_{t-1} + u_t,$$

$$(15b) \quad G_t = \gamma + \varepsilon(L)G_{t-1} + \omega(L)D_{t-1} + v_t.$$

The "hallmark" of the rational expectations modeling approach is the existence of a set of cross-equation restrictions which is implied by the underlying theoretical structure. In the present case, I obtain

$$(16) \quad \begin{aligned} \delta &= \alpha + \theta\gamma \\ \eta_i &= \begin{cases} \theta(\beta - \varepsilon_i) & i = 1 \\ -\theta\varepsilon_i & i = 2, \dots, n \end{cases} \\ \mu_j &= -\theta\omega_j & j = 1, 2, \dots, m. \end{aligned}$$

Thus, the equation set (16) restricts the way in which past government expenditure and past government deficits may influence present consumption expenditure. In particular, if the Ricardian equivalence proposition does not hold, past values of the government def-

icit should have explanatory power for consumption expenditure apart from their role in forecasting government spending. Consequently, a finding that the data do not do violence to the restriction set (16) yields some ground on which to argue that, to a first approximation, the joint assumption of rational expectations and Ricardian equivalence provides a plausible description of reality.

The empirical procedure is to estimate the system (15), subject to the restrictions (16) by the method of full-information maximum likelihood (FIML) to acquire estimates of the free parameters of the system ( $\alpha, \beta, \theta, \gamma, \varepsilon_1, \dots, \varepsilon_n, \omega_1, \dots, \omega_m$ ), which are  $n + m + 4$  in number. The method allows for nonlinear parameter restrictions within and across equations. The actual estimation was carried out in the TROLL computer package which utilizes the iterative hill-climbing technique developed by Davidon-Fletcher-Powell to maximize the likelihood function. The results of this estimation for the sample period extending from 1984:I to 1981:IV for the case of two lagged values of government spending and two lagged values of the government deficit are reported in Table 2.

Overall, the results appear to be encouraging for the joint hypothesis. Consider first the constrained estimates of the free parameters of the system. The estimated coefficient on the lagged value of consumption is highly significant and equal to unity, with the implication that—holding fixed the level of

<sup>b</sup>The coefficients are obtained by substitution of the constrained coefficient estimates into the set of restrictions (16).

government spending—private consumption expenditure follows a random walk process. The point estimate for the substitutability of public spending for private consumption equals .23 and is significantly different from zero at the 5 percent level. This result that government spending substitutes poorly for private spending implies that increases in government purchases of goods and services will have important expansionary effects on aggregate demand even in a setting where the government financing decision is irrelevant to the determination of real variables. In an expanded neoclassical model as in Hall (1978) or Barro (1981), to the extent that such increases in government spending are temporary in nature (for example, wartime expenditure), there would also be a stimulative

effect on real output as the induced rise in the real rate of return would call forth an intertemporal substitution of work effort from the future to the present. Note also that the point estimate of  $\theta = .23$  is roughly in accord with Kormendi's results.

The results indicate that government spending reacts to a process innovation in a cumulative—and borderline unstable—manner. Further, the level of government purchases appears to be positively related to past government deficits, with principal predictive power being confined to the first lagged value of the deficit. Given that government spending and deficits are characterized by positive serial correlation, this latter result may be rationalized along the lines in Barro (1981) or Finn Kydland and Edward Prescott (1980) by the recognition that optimal public finance would require that temporary increases in government spending should be financed by debt creation in an attempt to smooth tax rates over time and, thereby, minimize the deadweight loss due to distortionary labor income taxation.

Next, compare the unconstrained parameter estimates with the hypothesized values obtained by substituting the constrained estimates into the set of restrictions (16). It may be argued in a heuristic manner that the data do not contain substantial evidence against the joint Ricardian equivalence-rational expectations hypothesis if the unconstrained parameter estimates and the hypothesized parameter values do not differ by a substantial amount from one another. Inspection of these two columns in Table 2 indicates that all parameters carry the same signs and are roughly of the same order of magnitude. We should expect, therefore, that a formal statistical test will not lead to a strong rejection of the (joint) null hypothesis.

Turning to this point, since the unconstrained version of the system (15) has  $2(n+m)+3$  regressors and the number of free parameters in the system is equal to  $n+m+4$ , the log-likelihood ratio statistic  $-2\log_e(L_r/L_u)$  is distributed in large samples as a  $\chi^2(k)$  random variable with  $k = [2(n+m)+3] - (n+m+4) = n+m-1$  degrees of freedom, where  $L_r$  is the value of the

<sup>a</sup> $n = 2, m = 1$ .<sup>b</sup>See Table 2.

log-likelihood function under the constrained maximization and  $L_u$  is its value under the unconstrained maximization. A large discrepancy between the constrained and unconstrained values of the log-likelihood function results in a large value of the test statistic and evidence against the null hypothesis that the constrained model is true. For the case examined above where  $n = m = 2$ , the value of the log-likelihood ratio statistic is 4.281, substantially below the 10 percent critical value of the  $\chi^2(3)$  distribution, 6.25 (the implied marginal confidence level is 76 percent, so that the null hypothesis cannot be rejected at a significance level lower than 24 percent). Therefore, in this case, the data are incapable of rejecting the null hypothesis at conventional significance levels.

Notice that the least significant of the variables in the constrained estimation is the second lagged value of the deficit in the government purchases equation. A natural course would be to reestimate the model for the case of two lagged values of government spending and one lagged value of the govern-

ment deficit. The results of this estimation over the sample period 1948:I to 1981:IV are listed in Table 3. The constrained coefficient estimates maintain the same (or nearly the same) values and levels of statistical significance. The only exception is the first lagged deficit variable, the coefficient of which experiences an increase in its value and a fall in its estimated standard error. Again, the unconstrained parameter estimates and the values implied by the constrained estimates and the restriction set (16) always have the same signs and are similar in magnitude. In this case, the log-likelihood ratio statistic is distributed asymptotically as  $\chi^2(2)$  and takes on the value 4.280 which is still below the 10 percent critical value of the  $\chi^2(2)$  distribution, 4.61 (the implied marginal confidence level is 87 percent). Although the elimination of the two-period-past deficit raises the confidence level at which the null hypothesis can be rejected, it remains impossible to argue that the data provides evidence against the joint proposition of Ricardian equivalence and rational expectations at conventional levels of significance.

The values of the Durbin  $h$ -statistic in Tables 2 and 3 do not indicate the presence of a significant amount of autocorrelation in the estimated residuals of the consumption and government purchases equations. Nevertheless, a further check on the robustness of the results obtained above was implemented by expanding the lags of the government spending and deficit variables. Table 4 reports values of the associated log-likelihood ratio statistics as well as estimated values of the substitutability parameter,  $\theta$ .<sup>9</sup> In all cases, the null hypothesis under consideration cannot be rejected at the 10 percent level of significance. In one case,  $n = m = 6$ , it would be impossible to reject the null hypothesis at a significance level lower than 25 percent. The value of the substitutability parameter tends to rise with the number of included lags of government spending and deficits, to as much as .421 with the inclusion of two years of past spending and deficits. For the

cases  $n = m = 3$ ,  $n = m = 4$ , and  $n = m = 6$ , however, the substitutability parameter takes on the value  $\theta = .33$ , almost exactly the value found by Kormendi utilizing the conventional methodology. On the basis of these results we may come to the overall conclusions that the data do not appear capable of strongly rejecting the Ricardian equivalence theorem and that rises in government spending will only induce a partial *ex ante* crowding out of private consumption.

### III. Conclusion

This paper has investigated the question of fiscal impotence within an explicit rational expectations optimizing framework. Two questions were posed: To what extent does government spending induce an *ex ante* crowding out of private consumption expenditure? To what degree do the data contain evidence against the tax discounting hypothesis associated with the theoretical analysis of Barro (1974)? Public expenditure was seen to reduce private consumer expenditure on nondurables and services in the range of 23 to 42 percent, a range which is compatible with Kormendi's results. The values of the log-likelihood ratio statistics are too low to reject the joint rational expectations-Ricardian equivalence hypothesis at the typical 5 or 10 percent levels, a finding which adds some support to the earlier empirical work of Barro (1978), Kochin, Charles Plosser (1982), and Kormendi.

The new-classical school of macroeconomic policy stresses the real effects of government spending rather than the method by which such spending is financed. The primary effect of temporary increases in

government spending on output arise from the attempt by economic agents to smooth effective consumption levels over time. Hence, if  $0 < \theta < 1$ , this attempt will induce a reallocation of resources from other periods to the present which, in turn, will increase rates of return and cause an intertemporal substitution of work effort and a contemporaneous expansion of output. The empirical results of this paper suggest that this view of the effects of fiscal policy actions on the economy deserves at least some credibility, perhaps even the status of the working hypothesis.

### APPENDIX

The variable definitions and statistical sources are:

$C_t$  = real per capita consumer expenditure on nondurable goods and services;

$D_t$  = net real per capita deficit of federal, state and local governments;

$G_t$  = real per capita expenditures of federal, state and local governments.

Deflation of nominal aggregates is by the implicit price deflator (1972 = 100) and total population of the United States. All variables are taken from the Citibank economic database, "Citibase."

# General Equilibrium Computations of the Marginal Welfare Costs of Taxes in the United States

By CHARLES L. BALLARD, JOHN B. SHOVEN, AND JOHN WHALLEY\*

In recent years, increasing attention has been paid by public finance economists to the marginal excess burden (*MEB*)<sup>1</sup> per additional dollar of tax revenue. Estimates of *MEBs* stand in contrast to estimates of the welfare cost of taxes which are calculated by totally removing existing taxes and replacing them with equal yield lump sum taxes. Instead, an *MEB* estimate measures the incremental welfare costs of raising extra revenues from an already existing distorting tax. Earlier estimates of *MEBs* have either concentrated on particular portions of the tax system, or have employed partial equilibrium methods. Here, we examine the *MEB* of all major taxes in the United States, using a multisector, dynamic computational general equilibrium model. This allows us to calculate simultaneously the marginal welfare effects of individual income taxes, corporate taxes, payroll taxes, sales and excise taxes, and other smaller sources of revenue.

We find that the marginal excess burden of taxes in the United States is large. The welfare loss from a 1 percent increase in all distortionary tax rates is in the range of 17 to 56 cents per dollar of extra revenue, when we use elasticity assumptions that we consider to be plausible. Consequently, a public proj-

ect must produce marginal benefits of more than \$1.17 per dollar of cost if it is to be welfare improving. This suggests that many projects accepted by government agencies in recent years on the basis of cost-benefit ratios exceeding unity might have been rejected if the additional effects of distortionary taxes had been taken into account. The cost-benefit standard should be more stringent. Another implication of our results is that a tax reform that lowers tax rates by a relatively small amount might significantly reduce the total welfare costs of taxes.

We also calculate the marginal excess burden from increases in various parts of the tax system. Not surprisingly, we find that the *MEB* for a given part of the tax system is greater when the taxed activity is assumed to be more elastic. The *MEB* from capital taxes responds a great deal to the saving elasticity and the *MEB* from labor taxes responds a great deal to the labor supply elasticity. In general, it appears that the *MEBs* are greater for activities which face high or widely varying tax rates. These conclusions are, in general, in accord with those drawn from a simple, partial equilibrium model (see Edgar Browning). Such a model indicates that *MEBs* would be proportional to the elasticity of the taxed activity and proportional to the tax rate.

It is worthwhile to explain our treatment of public goods and the precise tax replacement experiment implicit in our calculations. The literature on the optimal provision of public goods due to Paul Samuelson (1954), Peter Diamond and James Mirrlees (1971a, b), Partha Dasgupta and Joseph Stiglitz (1972), and A. B. Atkinson and N. H. Stern (1974) sets out the conditions for the optimal quantity of a pure public good. Atkinson and Stern modify Samuelson's conditions to account for the excess burden of distortionary taxes used to finance public

\*Departments of Economics: Michigan State University, East Lansing, MI 48824; Stanford University, Stanford, CA 94305; University of Western Ontario, London, Ontario, N6A 5C2 Canada, respectively. An earlier version of this paper appeared as NBER Working Paper No. 1043. We thank Don Fullerton, Larry Martin, Paul Menchik, Joel Slemrod, Charles Stuart, and an anonymous referee for helpful comments, and Janet Stotsky for research assistance. This work was supported by the NBER Project on the Government Budget and the Private Economy and by the U.S. Treasury Department. Any errors are ours.

<sup>1</sup>For example, Edgar Browning (1976), Harry Campbell (1975), Ingemar Hansson and Charles Stuart (1983), and Dan Usher (1982).

goods provision. Although Atkinson and Stern are not concerned with calculating *MEBs* as such, their work is closely related to ours. They allow for complementarity between public goods and private goods, and, if complementarity is sufficiently great, their model can call for an even greater level of public goods than the simple Samuelson model. Our model does not allow for such complementarity since public goods do not enter household utility functions in our framework. In our model, the government uses its revenues to provide transfer payments to the household sector, and it makes exhaustive expenditures that do not directly affect consumer utility or the structure of production. If we were to extend our model to account for complementarity, our measure of *MEB* might be reduced.

Regarding the type of tax change experiment we undertake, it is worthwhile emphasizing that the questions we ask are *not* in the realm of what Richard Musgrave (1959) calls "differential incidence." Studies of differential incidence (including previous studies involving this model, such as Don Fullerton et al., 1981, and Fullerton, Shoven, and Whalley, 1983) hold constant the size of the government. When a distortionary tax is increased, there is an offsetting rebate. In this paper, we analyze what Musgrave would term "balanced budget incidence." We raise distortionary taxes and the government in the model uses the additional revenue for exhaustive expenditures. There is no lump sum rebate to consumers. The foregone alternative is a lower level of taxation rather than a lump sum tax.

#### I. A General Equilibrium Model of the U.S. Economy and Tax System: Structure and Data

To keep the focus of this paper on results and policy implications, only a brief overview of model structure is given here. We provide a detailed description of our model in chapters 3–7 of Ballard et al. (1985). First, we summarize the production side of the model. In any single period, there are 19 producer-good industries that use capital and labor in constant elasticity of substitution (*CES*) value-added functions. They also use

the outputs of other industries through a matrix of fixed input-output coefficients. The tax rates on labor for each industry are derived by taking payroll taxes and other contributions as a proportion of labor income, while the tax rates on capital for each industry are derived by taking corporate income, corporate franchise, and property taxes as a proportion of capital income. Each of these 19 producer goods is used directly for investment, for net exports, and for exhaustive government expenditures. In any period, consumers allocate their consumption among 15 consumer goods. The transformation of producer goods into consumer goods is represented by a matrix of fixed coefficients. This procedure is necessary because the goods classification of consumer expenditure data is different from the classification of the outputs of the 19 production sectors.

On the consumer side of the model, we have 12 consumer groups, which are distinguished by their money income<sup>2</sup> in 1973 (the basic data year for the model). Each consumer group has an initial endowment of capital and labor. Consumer decisions regarding factor supplies are made jointly with their consumption decisions. Each household at any point in time has a nested *CES* utility function of the form:

$$(1) \quad U = U \left[ H \left( \prod_{i=1}^{15} X_i^{\lambda_i}, l \right), C_f \right],$$

where  $H$  is the instantaneous utility function defined over current consumption commodities  $X_i$  and leisure  $l$ , and the function  $U$  determines the allocation between current welfare and expected incremental future consumption,  $C_f$ . The 15 current consumption commodities  $X_i$  are aggregated using a Cobb-Douglas function, whereas both  $U$  and

<sup>2</sup> These are incomes as defined for the 1973 *Consumer Expenditure Survey*. Money incomes exclude imputed income from home ownership, and sheltered capital income of various kinds. Even though we differentiate among consumers with this restricted definition of income, we do impute all kinds of capital income to every consumer group. Thus, each consumer group's income in our model calculations is greater than its narrowly defined money income.

$H$  are CES functions. Consumers are infinitely lived, so that there are no bequests.

The government collects taxes from the production and demand sides of the economy and uses the revenue in a balanced budget. The government purchases producer goods, makes direct transfer payments to consumers, and subsidizes government enterprises. A simple formulation of international trade closes the model.

In this model, we calculate a dynamic sequence of static equilibria. In essence, we examine a series of single-period equilibria, sequenced through saving decisions which change the time profile of the economy's capital stock. Saving in each period depends on the expected rate of return on saving in future periods. The simulations reported here use the assumption of myopic expectations.<sup>3</sup> Because of this assumption, the current period rate of return on capital and other current prices are all that we require to solve the utility-maximization problem for each household. With myopic expectations, the price of expected future consumption varies inversely with the current period rate of return, which consumers expect will apply to all future periods. Maximizing  $U$ , subject to a budget constraint, gives the desired level of  $C_t$  for each consumer. The demand of  $C_t$  is then translated into a demand for saving in the current period. The latter is, in turn, translated into a vector of investment demands for the 19 industry outputs.

We specify our model by calibrating to the same benchmark equilibrium data set for 1973 that is used in Ballard et al. A full updating of the data set to a more recent year would be costly and has not been done for our calculations; most of the main features of the U.S. tax system have not changed greatly in the last decade. However, the marginal rate of taxation of corporate capital income may now be lower than our data and techniques suggest. The data set uses five major sources. These are the 1973 Depart-

ment of Labor *Consumer Expenditure Survey*, the July 1976 *Survey of Current Business*, the Bureau of Economic Analysis Input-Output Matrix, unpublished worksheets of the U.S. Department of Commerce National Income Division, and the U.S. Treasury Department's Merged Tax File. In order to generate a consistent data set, a number of adjustments are made. All data on industry and government uses of factors are accepted as given, while the data on consumer factor incomes and expenditures are correspondingly adjusted. Tax receipts, transfers, and government endowments are accepted as given, and government expenditures are adjusted in order to yield a balanced budget. Similar adjustments ensure that supply equals demand for all goods and factors, and that trade is balanced.

The fully consistent data set defines a single-period benchmark equilibrium in transactions terms. These observations on values are then separated into prices and quantities by assuming that a physical unit of a good or factor is the amount that sells for one dollar. All benchmark equilibrium prices are thus \$1, and the observed values are the benchmark quantities.

The equilibrium conditions of the model are then used to determine the behavioral equation parameters consistent with the benchmark data set. This procedure calibrates the model to the benchmark data, in the sense that the benchmark data can be reproduced as an equilibrium solution to the model before any policy changes are considered. In order to implement this procedure, we specify the elasticities of substitution between capital and labor in each industry on the basis of econometric estimates in the literature. We also specify labor supply and saving elasticities (also based on literature sources), to which substitution elasticities in preferences are calibrated. Factor employments by industry are used to derive production function weights, and expenditure data are used to derive utility function weights. This calibration procedure ensures that, given the benchmark data, the various agents' behaviors are mutually consistent before we evaluate policy changes.

The elasticities of labor supply and saving are especially important parameters for our

<sup>3</sup>We have investigated the sensitivity of our results with respect to changes in the assumptions about expectations, using the procedure developed by Ballard and Lawrence Goulder (1982). We find that different expectational structures have little effect on the results.

results. There are a large number of estimates for the uncompensated elasticity of labor supply with respect to the real, net-of-tax wage. Elasticity estimates for males are mostly small and negative, ranging from  $-0.40$  to zero. George Borjas and James Heckman (1978) review these econometric studies and suggest a range between  $-0.19$  and  $-0.07$ . The estimates for females are more often positive, and can be large in absolute value. Mark Killingsworth (1982) finds that the elasticity estimates for females are mostly between  $0.20$  and  $0.90$  in cross-section studies. We use three values for the uncompensated labor supply elasticity. A value of  $0.15$  is our central estimate, and we also use elasticities of  $0.0$  and  $0.30$ . We calibrate these values by specifying the elasticity of substitution between present consumption and present leisure for the  $H$  function in equation (1) for each consumer.

The other key parameter is the elasticity of saving with respect to the real, after-tax rate of return, which we use to determine values for the elasticity of substitution between present consumption,  $H$ , and future consumption,  $C_f$ , for each consumer in the model.

There is considerable literature controversy regarding the value of the uncompensated saving elasticity. For a long time, the consensus appeared to favor a zero value for this elasticity, a proposition termed Denison's Law, after Edward Denison (1958). In more recent work, Michael Boskin (1978) has estimated this elasticity to be approximately  $0.3$  to  $0.4$ , although Lawrence Summers (1981) has shown that reasonable parameter values in life cycle model may imply saving elasticities between  $1.5$  and  $3.0$ . Each of these studies has problems of interpretation. In particular, for reasons outlined in the paper by David Starrett (1982), Summers's elasticity figures may be high. We focus on simulations using the values of  $0.0$  and  $0.4$  for the saving elasticity. We also consider a high value of  $0.8$ . As might be expected, the marginal excess burden estimates increase as the saving elasticity increases. However, the labor supply elasticity seems to be the more important parameter.

The value used for the real net-of-tax return to capital in the benchmark data is

important, since this value is used to calibrate preference parameters under the assumption of intertemporal utility maximization. It also determines the rate of time preference in the benchmark sequence of equilibria. We use  $4$  percent for the average value of this parameter, but each income class receives a net-of-tax return that depends on its own marginal tax rate.

The dynamic behavior of the model depends on the steady-state growth rate assumed for the benchmark equilibrium sequence. To derive this rate, we compare the amount of observed 1973 saving to the capital stock. This gives us a growth rate of the capital service endowment of  $2.89$  percent per year. We assume that labor (in effective units) grows at the same rate. Though labor endowments grow at this fixed annual rate in both the benchmark sequence and the revised sequence, the demand for leisure is endogenous. This implies that market labor supply growth may differ when prices change until balanced growth is reestablished. Though the capital stock grows at this rate in the benchmark sequence, endogenous saving implies that, in the revised case, capital services may grow at a different rate. The  $2.89$  percent labor growth rate is assumed to be equally divided between Harrod-neutral technical change and population growth. Our welfare measures of tax changes are adjusted to account only for the initial population size.

## II. Model Treatment of Taxes

The model incorporates each of the major taxes in the United States. In Table 1, we outline how these are modeled; summary information on the tax rates in the model is presented in Table 2. Mean factor and consumer tax rates across industries and commodities are reported, with indications of the dispersion in tax rates.

The treatment of each tax in the model reflects assumptions we make about the operation of the tax system. Thus, we combine the corporate and property taxes to produce an overall tax rate on capital income originating in each industry. We define these capital tax rates as a proportion of net-of-tax income; thus tax rates can exceed unity. The

TABLE 1—U.S. TAXES AND THEIR TREATMENT IN THE MODEL

Tax	Treatment in the Model	Difficulties of Model Treatment
1. Corporate taxes (including state and local) and corporate franchise taxes	Ad valorem tax on use of capital services by industry	Some argue for treatment as a lump sum tax; model treatment ignores role of financial instruments
2. Property taxes	Ad valorem tax on use of capital services by industry	Differential rates across jurisdictions ignored
3. Social Security taxes, Unemployment Insurance and Workmen's Compensation	Ad valorem tax on use of labor services by industry	Benefit related nature of contributions; arbitrary distinction between public and private insurance programs
4. Motor vehicles tax	Ad valorem tax on use of motor vehicles by producers	In practice, a yearly registration fee and not a purchase tax; averaging over jurisdictions
5. Retail sales taxes	Ad valorem taxes on purchase of consumer goods	Averaging of rates over states
6. Excise taxes	Ad valorem taxes on output of producer goods	Taxes often expressed as charge per unit physical measure such as volume
7. Other indirect business taxes and nontax payments to government	Ad valorem tax on output of producer goods	Payments depend on output levels by industry to only limited extent; averaging of rates over states
8. Personal income taxes (including state and local)	Linear function for each consumer where tax on capital affects industry allocation; 30 percent of savings currently deductible	Detailed deductions and exemptions not specifically considered in model

average tax rate on capital income at the industry level is about 0.97, which corresponds to a tax rate on gross capital income of just under 50 percent.<sup>4</sup>

In modeling the corporate tax, we follow the tradition of Arnold Harberger (1962, 1966) who treats it as a partial factor tax, even though more recently this has been the subject of active debate. Stiglitz (1973), for instance, has argued that if all marginal investments by firms are debt financed, the corporate tax operates as a lump sum tax. However, many features of corporate financial behavior remain unexplained, and we follow Harberger's procedure of treating the corporate tax as an ad valorem tax on capital, with average and marginal tax rates the same.

<sup>4</sup>These rate estimates do not incorporate the reductions in capital tax rates which were part of the 1981 Economic Recovery Tax Act and the further changes of the 1982 Tax Equity and Fiscal Responsibility Act. For a study of the effects of these changes in tax rates, see Fullerton and Yolanda Henderson (1983).

As a result, differences in capital income tax rates cause capital to be misallocated across industries.

In addition, the corporate tax affects saving decisions, since savers who acquire corporate equity indirectly pay these taxes on the return to their savings. Further distortions operate through the tax treatment of depreciation. While depreciation allowances operate at rates that are faster than true depreciation, they are calculated on a historical cost basis. Capital tax rates also include the investment tax credit. All these features combine to produce a pattern of tax rates by industry which is discriminatory.

A further key feature of our specification of capital tax rates is the assumption that average and marginal tax rates are the same. Fullerton (1984) has suggested a number of reasons why marginal and average rates need not be the same, and argues that under current laws, marginal rates are probably lower than average rates. Consequently, our specification may overstate marginal excess bur-

TABLE 2—LEVEL AND DISPERSION OF TAX RATES IN THE MODEL

Type of Tax	Sectors on Which Tax Is Levied	Weights	Weighted Tax Rate Statistics		
			Mean of Marginal Tax Rates	Standard Deviation	Coefficient of Variation <sup>b</sup>
Capital Taxes at Industry Level	19 Industries	Capital Use	0.970	0.729	0.752
Labor Taxes at Industry Level	19 Industries	Labor Use	0.101	0.009	0.092
Consumer Purchase Taxes	15 Goods	Total Consumption	0.067	0.140	2.101
Output Taxes	19 Industries	Output	0.008	0.035	4.612
Motor Vehicle Taxes	Intermediate Use of Motor Vehicles in 19 Industries	Use of Motor Vehicles	0.052	0.051	0.992
Personal Income Taxes <sup>a</sup>	12 Consumer Groups	Income	0.239	0.101	0.424

<sup>a</sup>Personal income tax rates are expressed as a proportion of gross income, whereas the other rates are expressed as proportions of net-of-tax capital income by industry, labor income by industry, etc.

<sup>b</sup>Coefficients of variation will not equal the quotients of the corresponding standard deviations and means because of rounding in the standard deviations and means.

dens as far as this portion of the tax system is concerned. The assumption of equality between marginal and average rates is less contentious in the case of tax rates on labor at the industry level, which we calculate using data on Social Security and other contributions.

We treat the property tax as a differential tax on capital by sector (similarly to the corporate tax). This falls most heavily on residential housing, but structures in other capital-using industries in the economy are also liable for the tax. As with the corporate income tax, both static and dynamic distortions occur.

Income tax rates differ substantially among consumers, with each of the 12 consumer groups facing a linear income tax schedule. Marginal tax rates rise from 0.01 for the poorest group to 0.41 for the richest.

The key distortions caused by the income tax affect factor supply decisions. It is widely recognized that the income tax distorts labor supply. In addition, the supply of new capital through saving is affected (by the "double" taxation of saving), although these effects are partially offset by the tax treatment of pensions and housing. We assume that 30 percent of saving is sheltered in this way. (This assumption is based on calculations using the 1976 *Flow of Funds Accounts*.) However, since saving is heavily concentrated in the

top tail of the income distribution, much of the saving in the economy occurs where the tax rates are highest.<sup>5</sup>

In addition to distorting factor-supply decisions, the income tax also has important features which distort choices among industries and commodities. The most prominent of these is the preferential treatment of housing that results from the absence of tax on the imputed income of owner-occupied housing. This is compounded by the preferential treatment for capital gains on houses.

Consumer sales and excise tax rates average about 6.7 percent in the model, and rates for most goods are reasonably low. There are three notable exceptions: the tax on alcoholic beverages is 87.5 percent, on tobacco, 95.8 percent, and on gasoline and other fuels, 29.5 percent.

Consumer sales taxes have a variety of effects. Even if the sales tax system covers all commodities evenly, it still distorts labor supply decisions. Additional distortions come from the nontaxation of food and other exempted items. Also, the specific excises on alcohol, tobacco, and gasoline are sharply

<sup>5</sup>Our model exaggerates this effect, since we do not capture life cycle differences among households. However, the evidence provided by Paul Menchik and Martin David (1983) indicates that lifetime saving is also concentrated.

discriminatory in our model, since we treat them (along with sales taxes) as ad valorem taxes. We recognize that this latter treatment is contentious. The taxes on alcohol and tobacco could be defended as Pigovian externality-correcting taxes. The gasoline tax is often viewed as a benefit-related fee for the use of the highway system. Because of these considerations, and because our formulation of the consumer's utility function may overstate the elasticity of demand for these products, we report two sets of results for the *MEB* from increases in consumer sales taxes. In the first, we evaluate the effect of an increase in the tax rate on every commodity. In the second, we raise only the tax rates on commodities other than alcohol, tobacco, and gasoline.

### III. Use of the Model in *MEB* Calculations

In our discussion of the various types of taxes, we have distinguished intertemporal distortions (that affect saving decisions) from intersectoral distortions (that affect allocations among industries or consumer goods). Many of the general equilibrium models that exist today can calculate only a single equilibrium. Consequently, they are poorly equipped to analyze the relative importance of intertemporal and intersectoral distortions. Our model allows us to assess intertemporal distortions as well as intersectoral ones. We calculate a sequence of equilibria, covering an arbitrarily long period of time. The equilibria are connected by endogenous saving decisions and exogenous growth of labor endowments.

In each single-period equilibrium, utility-maximizing consumers and profit-maximizing producers reach a competitive equilibrium where all profits are zero and supply equals demand for each good and factor. We use a variant of the Factor Price Revision Rule recently developed by Larry Kimbell and Glenn Harrison (1984) to calculate prices that satisfy these conditions for each time period. Although this algorithm is not guaranteed to converge, we have encountered no convergence problems, and this procedure is substantially faster than O. H. Merrill's (1972) algorithm, which we have used in earlier work on this model.

In each single-period equilibrium, markets are perfectly competitive, and there is no involuntary unemployment of factors, nor are there any externalities, quantity constraints, or barriers to factor mobility. The first equilibrium in the benchmark sequence replicates the 1973 equilibrium data set. In the no-policy-change case, subsequent equilibria are scaled-up versions of the initial equilibrium due to the balanced growth assumption. Prices remain constant, and all quantities grow at the same rate (the exogenous rate of growth of the effective labor force). When we alter tax parameters, we calculate a revised sequence of equilibria by computing a complete set of prices and quantities for each equilibrium in the sequence under an alternative tax policy. We estimate the changes in utility and income for each consumer group, changes in national income, and all new factor allocations among industries between pairs of comparable equilibria in the old (no-policy-change) and revised (after-policy-change) sequences.

Since we cannot compute an infinite sequence of equilibria, we calculate equilibria for a preselected number of years and then use a termination term. The welfare evaluation of the termination term is only correct if the economy is on a steady-state growth path, as is the case in our base-case sequence of equilibria. In a revised-case sequence, the tax change generates a transitional path that approaches a new steady-state growth path and the termination term will only be approximately correct. The accuracy of this approximation becomes better as the economy approaches the new steady-state growth path. In our calculations of marginal excess burden, the changes in relative prices are small since the tax changes are small. We calculate an extremely close approximation by computing our equilibria 100 years into the future. These are spaced five years apart, giving us a sequence of 21 equilibria.

In earlier applications of our model, the government spends any extra tax revenues it receives on both additional transfer payments to consumers and purchases of goods and factors. However, it is easier to interpret the results of this paper if transfer payments do not change. Consequently, for the results reported here, we have changed the model

such that the level of real transfer payments of each consumer group remains the same in each period of the revised-case equilibrium sequence compared to the corresponding period of the base-case sequence.

Our objective is to compare the dollar value of the loss of consumer welfare resulting from an increase in distortionary taxes with the amount of revenue that the tax increase generates. For the loss of consumer welfare, we calculate the present value of a stream of Hicksian equivalent variations. Each of these is calculated using contemporaneous utility in comparable base and revise equilibrium calculations, as described in chapter 7 of Ballard et al. It should be noted that our consumer utility functions do not incorporate public goods. The implicit assumption is that public goods enter utility in a separable manner. We want to compare the dollar value of the loss in consumer utility from leisure and goods due to the tax with the revenue collected by the increase in the tax.

In order to get a similar present value figure for the change in revenue, we correct for changes in relative prices over time, since the dollar increase in revenue in one period is not strictly comparable with the dollar increase in revenue in another period. The model assumption is that government purchases of goods and factors are characterized by constant expenditure shares. Instead of using a Laspeyres price index or some other index to correct for relative price changes, we use the expenditure function associated with the implicit Cobb-Douglas utility function of the government. A different assumption about the pattern of government expenditure could alter the results, since the government does not spend marginal tax revenue in the same way that consumers would have spent it if it had been returned to them in lump sum form.

#### IV. Results

The marginal excess burden calculations produced by the model are shown in Tables 3 and 4. Table 3 shows the *MEB* from raising all marginal tax rates by 1 percent for different saving and labor supply elasticities. Table 4 reports *MEB* estimates from raising

TABLE 3—MARGINAL EXCESS BURDEN PER ADDITIONAL DOLLAR OF REVENUE FOR U.S. TAXES

Labor Supply Elasticity	Saving Elasticity		
	(i) 0.0	(ii) 0.4	(iii) 0.8
(i) 0.0	.170	.206	.238
(ii) 0.15	.274	.332	.383
(iii) 0.30	.391	.477	.559

additional revenue from alternate portions of the tax system for different elasticity configurations.

Estimates of marginal excess burdens in Table 3 are substantial. They indicate that the transfer of an additional dollar to the government causes a deadweight loss in the range of 17 to 56 cents. This means that additional public expenditures ought to be undertaken only if their marginal benefits are at least 17 percent greater than the revenues needed to fund the project, if it has to be financed by additional distorting taxes.

As might be expected, marginal excess burdens are greater when higher elasticity values are used. The results are more sensitive to changes in the uncompensated labor supply elasticity than to changes in the saving elasticity. We would place the most confidence in our estimates using the middle elasticities (.4 and .15). An uncompensated saving elasticity of 0.8 and an uncompensated labor supply elasticity of 0.3 have been added to Table 3 mainly to illustrate the sensitivity of the results to changes in these parameters.

In Table 4, we report *MEB* estimates for cases where additional revenues are raised through the major tax subgroups. For these cases, we only use the labor supply elasticities of 0.0 and 0.15 and saving elasticities of 0.0 and 0.4 as parameter value combinations.

For the most part, the various parts of the tax system do not generate vastly different *MEBs*. However, we can generally say that the more elastic activities have higher *MEBs*. With a saving elasticity of 0.4, capital taxes lead to the greatest *MEBs*. With a labor supply elasticity of zero, the labor taxes at the industry level cause relatively small amounts of marginal distortion. If we focus on our central case (with elasticities of 0.4

TABLE 4—MARGINAL EXCESS BURDEN FROM RAISING EXTRA REVENUE FROM SPECIFIC PORTIONS OF THE TAX SYSTEM

Uncompensated Saving Elasticity:	0.0	0.4	0.0	0.4
Uncompensated Labor Supply Elasticity:	0.0	0.0	0.15	0.15
All Taxes	.170	.206	.274	.332
Capital Taxes at Industry Level	.181	.379	.217	.463
Labor Taxes at Industry Level	.121	.112	.234	.230
Consumer Sales Taxes	.256	.251	.384	.388
Sales Taxes on Commodities other than Alcohol, Tobacco, Gasoline	.035	.026	.119	.115
Income Taxes	.163	.179	.282	.314
Output Taxes	.147	.163	.248	.279

for saving and 0.15 for labor supply), we see that capital taxes, consumer sales taxes, and income taxes cause the greatest distortion, followed by output taxes and labor taxes at the industry level. This is almost exactly the same ranking that we found for *average* excess burdens in our earlier study (1982, Table 10).

Simple models would lead us to expect that *MEBs* would be high when activities are taxed at high or widely dispersed rates. This is borne out by our results. The labor tax rates at the industry level are fairly low and rather uniform among sectors, and the *MEBs* associated with these taxes are low. Capital tax rates are high and widely dispersed (see Table 2). Except in the case of a zero saving elasticity and a labor supply elasticity of 0.15, capital taxes have among the highest *MEBs*. We can also see the point about high and dispersed tax rates causing large *MEBs* if we look at the results for consumer sales taxes. When we raise all sales and excise taxes including the very high taxes on alcohol, tobacco, and gasoline, we have high *MEBs*. However, when we raise only the low taxes on the other commodities, we end up with very modest *MEBs*.

## V. Conclusion

In this paper we report estimates for the United States of the marginal excess burden of raising additional tax revenues. We use a dynamic sequenced numerical general equilibrium model of the U.S. economy and tax system which we have previously used to analyze specific policy proposals, such as

corporate tax integration or a move towards a consumption tax. Estimates are obtained by increasing tax rates for existing distortionary taxes.

The subject of marginal welfare costs of taxes has been discussed in the past by Harry Campbell, Browning, Dan Usher, and Charles Stuart (1984). Our contribution is in investigating this subject through a large-scale numerical general equilibrium model of the U.S. economy and tax system, incorporating all major U.S. taxes.

The central theme emerging from results is that the marginal welfare costs from raising existing distorting taxes in the United States are large, in the range of 17 to 56 cents. This has important implications for a range of policy issues. In the cost-benefit area, if a public project must be financed by distortionary taxes, the additional excess burden of these taxes should be taken into account. If this deadweight loss is as large as we suggest, it is possible that many projects accepted in recent years on the basis of favorable cost-benefit ratios should not have been undertaken. In approaching tax reform, these results suggest that a large portion of the potential welfare gains from removing distortionary taxes can be realized by a modest reduction in tax rates. Tax rate changes may, therefore, be more important than the structural reform of the tax system. In evaluating the redistribution-efficiency tradeoff in policy design, additional transfers financed at the margin by raising distorting taxes become very costly.

The issue of the marginal welfare cost of distortionary taxation has attracted increas-

ing attention during the last decade. Campbell estimated that the marginal excess burden of Canadian commodity taxes is about 24 cents. Browning reached a similar conclusion in a brief discussion of commodity taxes, but focused primarily on labor income taxes. Browning estimated that the *MEB* of these taxes is in the range of 9 to 16 cents. Browning made the conservative assumption that the compensated labor supply elasticity is 0.2. This value of the compensated elasticity is close to the values that we have when we assume that the uncompensated elasticity is zero. When we use the zero elasticity, our *MEB* estimates are only slightly higher than those of Browning. Stuart, like Browning, focuses on distortions of the labor supply decision. In his central simulations, using Browning's elasticity value, he finds *MEBs* in the range of 20.7 to 24.4 cents. Ingemar Hansson and Stuart have calculated a wide range of *MEBs* for Sweden. Their central estimates are much higher than ours or those of Browning, ranging from 69 cents to \$1.29. However, the difference can be explained by the fact that their central estimates incorporate the extremely high marginal tax rates (around 70 percent) that exist in Sweden. When Hansson and Stuart leave the rest of their model unchanged but assume marginal tax rates of 40 percent, their central case yields *MEB* estimates of from 7 to 16 cents. We feel that all of these studies point to the general conclusion that marginal excess burdens are fairly substantial. It may be too early to say that there is a consensus on this issue, but we do feel that there is growing evidence that *MEBs* may be in the range of 15 to 50 cents for an economy like that of the United States. We hope that the large estimates we report will contribute to future debate on tax reform in the United States and to a discussion of possibly modifying the cost-benefit criterion for public goods evaluation.

# The Use of Protection and Subsidies for Entry Promotion and Deterrence

By AVINASH K. DIXIT AND ALBERT S. KYLE\*

Artificial barriers to international trade and natural barriers to entry are both important features of certain imperfectly competitive high-technology industries, such as aerospace and computers. The effort by the European Airbus consortium to compete with Boeing in the market for intermediate-range commercial jets is the best known instance. It has been argued that protection of the Airbus' home market, and subsidies from the partner governments, allow the consortium to recover a significant fraction of the huge sunk costs of developing the Airbus. It has also been argued that without such support, and perhaps, also without access to Boeing's home market, the entire project would not be viable. In the United States, the protection and subsidies are regarded as unfair practices, requiring countermeasures.<sup>1</sup> A similar argument has been made about Japan's entry into the markets for 16K and 64K RAM microchips. The boot may be on the other foot for the 256K and megabit generations, with Japan dominant and the United States attempting entry.<sup>2</sup>

The aim of this paper is to begin analysis of the functioning of such markets and the role of policies towards them. To model the issues adequately, the potential for strategic behavior on part of both governments and firms must be taken into the account. Furthermore, it is important to recognize that the strategies of governments interact with

those of firms. The appropriate model is therefore a game-theoretic one, with the governments and the firms as the players.

The games we study differ in the order in which the players move. The issue is not merely, or even primarily, one of timing. It is whether one player can make a strategic precommitment of policy choice that affects subsequent choices of others to his own advantage. The availability of such moves in practice will depend on particular features of governmental and international institutions. Here we merely make different assumptions in this regard and compare the outcomes, thus determining the effects that particular strategies would have when available.

All the games have one common feature. The players who move earlier are aware of the nature of the game to follow, and correctly forecast the outcomes of those stages when computing the consequences of their own current actions. Therefore the games are solved backwards: the optimal actions at the last stage are calculated for all conceivable patterns of previous actions, these are used in determining the optimal choices at all penultimate-stage situations that can arise, and so on. The solution of the game as a whole has the property of rational expectations, and is commonly called a (subgame) perfect equilibrium.<sup>3</sup>

The particular theoretical model, and its notation, are suggested by the Airbus example. This should not be taken literally; we make several restrictive assumptions, so as to highlight and illustrate the strategic aspects in the simplest possible format. In the concluding section we will comment on the consequences of relaxing some of these assumptions.

<sup>2</sup>*The Economist*, June 19, 1982, Survey, p. 14.

<sup>3</sup>See Reinhard Selten (1975). A simplified exposition adequate for our concerns can be found in Dixit (1982).

We assume that there are only two countries and two firms. One of the firms is an incumbent (i.e., its sunk costs have already been incurred), located in one of the countries (*US*). The other firm is a potential entrant located in the other country (*EC*). The analysis is partial equilibrium in nature, that is, income effects are ignored and factor prices are exogenous. The objective of each firm is to maximize its profit. The objective of each government is taken to be the standard criterion of social welfare in partial equilibrium ignoring distribution, that is, the sum of *domestic* consumers' and producers' surpluses.

To simplify further, we restrict the policy choices. Each government has an all-or-nothing trade policy choice: free trade or complete prohibition of all imports in the industry. Similarly, when the *EC* government uses a subsidy policy, the choice is one of financing all or none of the sunk costs of its firm. The advantage of these restrictions is that we can use the "reduced-form" outcomes of the price and output decisions made by the monopolists or duopolists in the equilibrium consequent upon the discrete policy choices. The binary comparisons of profits and surpluses then govern the decisions to be made. Thus we are not tied down to any specific assumption such as Cournot or Bertrand behavior for the duopoly.<sup>4</sup>

The operation of the model, and the results, are in general conformity with economic intuition drawn from both industrial organization and international trade. The inability of firms to appropriate all of consumers' surplus can justify a policy to alter an oligopolistic market outcome even from the viewpoint of worldwide efficiency.<sup>5</sup> For a single country, the capture of any monopoly rents on behalf of its own residents can make it desirable to pursue policies that favor its

own firms and harm foreign ones.<sup>6</sup> When other governments are simultaneously pursuing trade policies, a prisoner's dilemma can arise at the policy level.<sup>7</sup> In our model, all these possibilities exist, but they take on new forms because of the irreversibility of entry. The timing of policy actions, and the degree of commitment to them, become crucial. Therefore these are the aspects we emphasize.

In Section I, the model is specified in more detail, and in Sections II–V its implications for strategic uses of policies towards entry are examined. We see how and when such policies promote national advantage. We find that the *EC* government gains from protectionist entry-promotion whenever entry occurs with such a policy but not without it. We also examine the implications for world welfare. As a general tendency, protection for entry promotion is harmful to the world, and countermeasures that deter such a policy are beneficial. Subsidies as instruments of entry promotion are generally more desirable from a world viewpoint; countermeasures against them are either ineffective or harmful.

In Section VI we indicate how the approach developed here can be adapted to extend the model by changing some of the special assumptions.

## I. Structure and Notation

Consider a homogeneous good that can be produced by a firm after it has undertaken a preproduction (sunk) expenditure  $K$ , at constant unit production cost  $c$ . International cost differences are ignored so as to focus on strategic interactions. There are two markets, *US* and *EC*, each with its own demand curve, and no resale by third parties. There is an incumbent *US* firm and a potential *EC* entrant firm.

<sup>4</sup>For a different approach, see Douglas Curtis (1983). He considers entry promotion with particular solution concepts, but does not consider strategic behavior by the incumbent firm or government.

<sup>5</sup>See Michael Spence (1976), and Dixit and Joseph Stiglitz (1977).

<sup>6</sup>See James Brander and Barbara Spencer (1984), Jonathan Eaton and Gene Grossman (1983), and surveys in Dixit (1984), and Grossman and David Richardson (1984).

<sup>7</sup>See Harry Johnson (1954).

In the *US* market, let  $PU_1$  = excess of revenue over production cost for a monopolist,  $PU_2$  = excess of revenue over production cost for each duopolist,  $SU_1$  = consumers' surplus under monopoly, and  $SU_2$  = consumers' surplus under duopoly. Consumers' surplus is measured with reference to some fixed price higher than any which arises in the market. For a nontrivial problem the demand is positive at price  $c$ . Then  $PU_1 > 0$  and  $SU_1 > 0$ . Also  $PU_2 \geq 0$  since zero production is always feasible. More importantly,

$$(1) \quad PU_1 \geq 2PU_2,$$

since a monopolist can always mimic the actions of two duopolists, and

$$(2) \quad 2PU_2 + SU_2 > PU_1 + SU_1,$$

assuming closed-economy duopoly is socially preferable to monopoly (because of higher output and lower price). This holds for a wide range of duopoly equilibrium concepts, including the familiar Bertrand and Cournot ones, so we do not need to specify any particular duopoly model. In Bertrand competition, for example, price equals production cost  $c$ , so  $PU_2 = 0$ .

In the *EC* market, we define  $PE_1$ ,  $PE_2$ ,  $SE_1$ , and  $SE_2$  in an analogous manner; require  $PE_1 > 0$ ,  $SE_1 > 0$ ,  $PE_2 \geq 0$ ; and have

$$(3) \quad PE_1 \geq 2PE_2,$$

$$(4) \quad 2PE_2 + SE_2 > PE_1 + SE_1.$$

Equilibrium is the outcome of a game played by three players: the *US* government, the *EC* government, and the potential entrant *EC* firm.<sup>8</sup> The two governments choose as their actions either free trade or protection, where "protection" is defined as the complete prohibition of imports. The *EC*

government decides whether to subsidize its firm's sunk costs. The *EC* firm decides whether to enter. The eight combinations of trade policy and entry decisions generate six different possible outcomes because *US* trade policy does not affect the outcome when the *EC* firm chooses not to enter. The six outcomes are the following:

*Autarky (AUT)*: The *EC* firm enters and both governments protect. Each market is served by its own monopoly firm.

*Protected Entry (PRE)*: The *EC* firm enters, the *EC* government protects, and the *US* government has free trade. There is duopoly in the *US* market and a monopoly by the *EC* firm in the *EC* market.

*Free Trade Duopoly (FTD)*: The *EC* firm enters and both governments choose free trade. There is duopoly in both markets.

*US Monopoly (MON)*: The *EC* firm does not enter, the *EC* government has free trade, and *US* government policy does not matter. The *US* firm has a monopoly in both markets.

*US Protection (USP)*: The *EC* firm enters, the *US* protects, and the *EC* has free trade. The *US* firm has a monopoly in the *US* market, and there is duopoly in the *EC* market.

*Irrational Protection (IRR)*: The *EC* firm does not enter, the *EC* protects, and *US* trade policy does not matter. There is monopoly in the *US* market, and the *EC* market is not served at all.

The objective of each government is to maximize the sum of domestic firm profits and domestic consumers' surplus. The objective of the *EC* firm is to maximize profits (net of sunk costs).

The value of the six outcomes to the three players is summarized in Table 1. Of these six outcomes, it is immediately obvious that the sixth outcome, "irrational protection," never arises as a perfect equilibrium outcome of the game. By choosing free trade when

<sup>8</sup>The *US* firm is a player in the "background" game of duopoly that is played if entry occurs. But it has already sunk its  $K$  and has no strategic choices, so it is not modeled explicitly.

TABLE 1—VALUES OF OUTCOMES TO THE THREE PLAYERS

Outcome	Player		
	US Government	EC Government	EC Firm
Autarky ( <i>AUT</i> )	$SU_1 + PU_1$	$SE_1 + PE_1 - K$	$PE_1 - K$
Protected Entry ( <i>PRE</i> )	$SU_2 + PU_2$	$SE_1 + PE_1 + PU_2 - K$	$PE_1 + PU_2 - K$
Free Trade Duopoly ( <i>FTD</i> )	$SU_2 + PU_2 + PE_2$	$SE_2 + PE_2 + PU_2 - K$	$PE_2 + PU_2 - K$
US Monopoly ( <i>MON</i> )	$SU_1 + PU_1 + PE_1$	$SE_1$	0
US Protection ( <i>USP</i> )	$SU_1 + PU_1 + PE_2$	$SE_2 + PE_2 - K$	$PE_2 - K$
Irrational Protection ( <i>IRR</i> )	$SU_1 + PU_1$	0	0

protection would not lead to entry by the *EC* firm, the *EC* government achieves (at worst) the superior outcome, "US monopoly."

In strategically interesting cases, the outcome of the game depends upon how the three players order the remaining five outcomes. For each player, several orderings consistent with Table 1 are possible.

## II. Worldwide Optimality

Worldwide social surplus, defined as the sum of world consumers' surplus and world producers' profits, is measured by adding together the objectives the *US* government and the *EC* government. Using this measure of social optimality, several rankings of the outcomes in Table 1 are possible, but these rankings do satisfy certain constraints. Because domestic duopoly is better than domestic monopoly, free trade duopoly is preferred to protected entry (by equation (4)) and to *US* protection (by equation (2)), and both of these outcomes are preferred to autarky. Furthermore, *US* monopoly is preferred to autarky since the *EC* firm's sunk costs do not have to be incurred, and to irrational protection since a monopoly in the *EC* market is better than no market at all. Thus, the socially best outcome is either free trade duopoly (if entry is desirable) or *US* monopoly (if entry is not desirable). The former is optimal provided

$$(5) \quad 2PU_2 + SU_2 + 2PE_2 + SE_2 - K > PU_1 + SU_1 + PE_1 + SE_1,$$

and the latter otherwise. Neither involves any protection, but the attainment of *FTD*

can require a jointly financed subsidy to induce entry.<sup>9</sup>

Even this optimality is second best, arising from an inability of the governments to bargain efficiently with the *US* monopolist in the first place. If efficient bargaining were allowed, both governments would "bribe" the *US* monopolist to supply the quantity demanded at marginal cost *c* in their respective domestic markets. Entry would never occur.

Inequality (5) is more likely to be satisfied (i) the more competitive the duopoly, and (ii) the lower the sunk cost. In any actual instance, these can work in opposite ways. In the aircraft industry, for example, the competition between Boeing and Airbus is fierce, but sunk costs are large. Considering the size of the world market, however, our presumption would be that in most industries (5) would hold, that is, *FTD* would be better than *MON*.

Later we will come across similar comparisons. From a world viewpoint, *PRE* is preferred to *MON* if

$$(6) \quad 2PU_2 + SU_2 - K > PU_1 + SU_1,$$

and *USP* is preferred to *MON* if

$$(7) \quad 2PE_2 + SE_2 - K > PE_1 + SE_1.$$

In each of these, the sunk cost is compared to the gain in total surplus in only one of the

<sup>9</sup>This assumes that the subsidy is financed with non-distorting taxes. Otherwise, (5) must be modified by subtracting the deadweight loss associated with the taxes from the left-hand side.

markets. Thus (6) and (7) are less likely to be satisfied than is (5). For a high sunk cost industry like aircraft, it seems likely that (6) and (7) would not hold.

### III. Nonstrategic Trade Policy Choices

We provide a reference point for the analysis of strategic trade policy choices by first considering a game in which they have no scope. This is done by placing the firm's entry decision first, and the governments' policies later. Such a game will be played if the governments are in fact unable to make credible policy commitments. We number this as game 1, and call it the reference game.

As explained above, the second stage is solved first. If the firm stays out, the *EC* government will choose free trade, the *US* policy will be immaterial, and the outcome will be *MON*. If the firm enters, a subsidy is irrelevant, but the trade policies of the governments interact as shown in Table 2.

Reference to Table 1 shows that each government has a dominant strategy (and therefore the order of their moves is immaterial). For example, the *US* government prefers protection if

$$(8) \quad PU_1 + SU_1 > PU_2 + SU_2,$$

and free trade otherwise. When the *EC* policy is protection, these are just the *US* payoffs from the respective choices. When the *EC* policy is free trade, the duopoly profit in that market,  $PE_2$ , is added to each side to get the *US* payoffs, and the comparison is unaffected. Note how our assumptions of constant marginal costs, and no international resales, separate the markets and yield this result. Similarly, the *EC* government's dominant policy is protection if

$$(9) \quad PE_1 + SE_1 > PE_2 + SE_2,$$

and free trade otherwise. Since these choices are determined by the sum of consumers' surplus and domestic firm profits in the domestic market alone, we call them the *domestically preferred trade policies*. There are

TABLE 2—POST-ENTRY TRADE POLICY GAME

US	EC	
	Protection	Free Trade
Protection	<i>AUT</i>	<i>USP</i>
Free Trade	<i>PRE</i>	<i>FTD</i>

four possible combinations. The two countries may have different domestically preferred policies either because duopoly solution concepts differ (on account of, say, different antitrust policies), or because the demand curves in the two countries have different shapes. At any rate, it is necessary to consider all four combinations of domestically preferred policies, even though only the symmetric ones will be relevant when the two markets are identical.

We mention in passing the possibilities for some commonly used solution concepts. If the duopoly is collusive (price and quantities same as in monopoly), the domestically preferred policy is protection. If the duopoly is Bertrand (price equals  $c$ ), it is free trade. For a Cournot duopoly, routine calculations show that the domestically preferred policy is protection with a linear demand curve ( $p = a - bq$ ,  $a > c$ ), and free trade with an exponential demand curve ( $p = ae^{-bx}$ ,  $c = 0$ ).

Now the *EC* firm knows that, if it enters, each government will choose its domestically preferred policy. Therefore it will assume these policies to test whether entry yields positive profit (net of sunk costs). This depends on the size of  $K$ . We therefore have another dimension of classification, namely the necessary and sufficient conditions for profitable entry. The four interesting categories follow:

- (10) Protection (of the *EC* market) and Access (to the *US* market):

$$\max(PE_1, PE_2 + PU_2) < K < PE_1 + PU_2;$$

- (11) Protection:  $PE_2 + PU_2 < K < PE_1;$

- (12) Access:  $PE_1 < K < PE_2 + PU_2;$

TABLE 3—OUTCOMES OF TRADE POLICY GAMES

Conditions for Profitable Entry	Domestically Preferred Policies			
	US Protection EC Protection	US Free Trade EC Protection	US Protection EC Free Trade	US Free Trade EC Free Trade

Note: The order of play:

1. Reference Game: The EC firm makes its entry decision first; the governments choose their (domestically preferred) policies later.

2. The Entry Promotion Game: The EC government chooses its trade policy first, then the EC firm makes its entry decision, and finally the US government chooses its (domestically preferred) policy.

3. Entry Deterrence by Commitment: The US government chooses its trade policy first, the EC government next, and the firm's entry decision is last.

4. Threats and Promises: The US government chooses a policy rule first, but it can specify a policy choice conditional on the policy choice made by the EC government at the second stage. The EC firm's entry decision is last.

<sup>a</sup>These outcomes are instances of entry promotion through protection.

<sup>b</sup>If the order of play of the EC firm and the US government is reversed, the outcome changes to *PRE* if the US government prefers *MON* to *FTD*; in all other cells this change of order does not affect the outcome.

<sup>c</sup>When the outcome is *MON*, the US policy is one of "entry deterrence."

<sup>d</sup>When the outcome is *FTD*, the US policy is one of "dissuaded entry promotion."

<sup>e</sup>When the outcome is *FTD*, it results from an "optimal promise" by the US government.

<sup>f</sup>When the outcome is *FTD*, it results from an "optimal threat" by the US government.

<sup>g</sup>When the outcome is *FTD*, it results from (i) an "optimal threat" if the US government prefers *PRE* to *MON* (i.e., the outcome of game 3 is *PRE*), and (ii) an "optimal promise" if the US government prefers *MON* to *PRE* (i.e., the outcome of game 3 is *MON*).

### (13) Protection or Access:

$$PE_2 < K < \min(PE_1, PE_2 + PU_2).$$

Note that the separate cases of Protection and Access are mutually exclusive, that is, only one arises for each given set of values of  $PE_1$ ,  $PE_2$ , and  $PU_2$ . We omit the categories where neither protection nor access is needed

( $K < PE_2$ ), and where both are not sufficient ( $K > PE_1 + PU_2$ ), since the role of strategic trade policies is not of interest in these cases. The latter will become relevant in Section V, where subsidies can be employed to promote unprofitable entry if the increase in consumers' surplus is large enough.

Considering the domestically preferred policies and the conditions of entry together, there are sixteen cases. We provide a table of

outcomes for completeness. But to avoid excessive taxonomy, we focus attention on a few cases of special interest, and then state some general results.<sup>10</sup>

The outcomes of games involving trade policies are shown in Table 3. Recall that the reference game has number 1. In the last column, for example, both domestically preferred policies are free trade. Therefore entry occurs when access to the *US* market suffices for profitability (Access, and Protection or Access) and the outcome is *FTD*. There is no entry in the other two cases, and the outcome is *MON*.

#### IV. Strategic Use of Trade Policies

Now we modify the reference game by allowing one of the governments to move first and make an irreversible, precommitted, policy choice. We then examine how such policies can be used for entry promotion by the *EC* government and deterrence by the *US* government. This section considers trade policies; the role of subsidies is taken up in the next section.

Precommitment yields new outcomes only to the extent that the chosen policy differs from the domestically preferred one. We shall see how such a commitment can be desirable to the government making it. But its credibility is problematic, since after the entry decision is made, the government has the incentive to reverse its choice. In practice there are devices that make such reversals costly; examples are constitutional provisions, automatic administrative procedures, the power of the special interests that favor the committed policy, and the government's reputation. Their reliability is a matter of degree. The question of which government is better placed to seize the initiative and make a commitment is also open. Theory at this level of generality can only show the consequences of the alternative possibilities in these matters, and that is the approach we take.

We consider three games of this kind. The first concerns entry promotion, and is numbered 2 in the table of outcomes (the reference game being number 1). Here the *EC* government moves first and chooses its trade policy. The *EC* firm moves second and decides whether to enter. The *US* government moves last and chooses its (domestically preferred) policy. (Reversing the last two stages would produce a different game, but in all cases its outcomes are Pareto worse, i.e., worse for all players, or the same. Thus, given that the *EC* government moves first, the *US* government would choose to move third rather than second. Therefore the order we have assumed is appropriate.)

Game 3 considers entry deterrence. The *US* government moves first, and chooses protection or free trade. The *EC* government moves second to choose its trade policy, and the *EC* firm's entry decision is last. (Reversing the last two stages would not be in the interests of either the *EC* government or the *EC* firm.)

Game 4 is similar, but the *US* government at the first move has an additional choice. It can precommit to a policy rule, which specifies a choice of protection or free trade conditional on the action taken by the *EC* government at its move. Such conditional rules can be of two kinds, "matching," defined as protection when the *EC* policy is protection and free trade when the *EC* policy is free trade, and "reversing," defined as protection when the *EC* policy is free trade and free trade when it is protection. The reversing policy is, however, never optimal because each government prefers that the other choose free trade and a reversing policy thus encourages the *EC* government to be protectionist which the *US* government does not want. The outcome of the conditional commitment game, if different from the unconditional one, must therefore be the result of a matching policy. Depending on circumstances, this can act as a threat (we will protect our market if you protect yours), or a promise (we will practice free trade if you do). In reality, such policies can be found in the form of reciprocity legislation or procedures, but their credibility is again open to

<sup>10</sup> Details of the arguments concerning trade policies (summarized in Table 3) can be found in our earlier paper (1983).

doubt. The earlier remarks on this issue apply here, too.

It is clear from Table 3 that the outcomes of games 2, 3, and 4 are in many cases different from those of the reference game. These different outcomes result from strategic policies which illustrate various strategic themes: entry promotion, entry deterrence, dissuasion, threats and promises. In the rest of this section we discuss these themes, illustrate them with specific cells from Table 3, and point out general tendencies for world welfare. Here we will not compute perfect equilibria in detail from the game trees. The verbal arguments are usually evident enough, and the interested reader can easily construct the details.

#### A. Entry Promotion

In the reference game, *MON* is in some cases the outcome even though a shift in *EC* policy from free trade to protection (holding *US* policy constant) makes entry profitable. In game 2, the *EC* can commit to protection and thus promote entry. In fact, the *EC* government will always make such a commitment in these cases. The simple explanation is that the *EC* market is going to be monopolized anyway, by the *US* firm if entry does not occur and by the protected *EC* firm if entry does occur. Since no gain or loss in consumers' surplus is at stake, the only question is whether a protected *EC* firm can make a profit, as a domestic monopolist if the *US* market is closed, or as both a domestic monopolist *cum* exporting duopolist if the *US* market is open.

Entry promotion shifts the outcome from *MON* to *AUT* when the *US* policy is protection, and from *MON* to *PRE* when the *US* policy is free trade. While the shift from *MON* to *AUT* always lowers world surplus, a shift from *MON* to *PRE* raises world surplus if inequality (6) is satisfied. Thus we cannot state as a universal rule that strategic entry promotion lowers world welfare. There is some presumption that it does so when sunk costs are large relative to the *US* market alone or when a *US* duopoly is not very

different from a monopoly (because, say, collusion is easy).

*Example:* Consider the case where both governments' domestically preferred policy is free trade, and profitable entry by the *EC* firm requires both protection of the *EC* market and access to the *US* market. In obvious notation, this is cell (1,4) in Table 3. This case can arise when the duopoly is very competitive and the sunk costs are large, and is therefore of special interest for the aircraft industry. In the reference game, the firm knew that protection would not be provided after entry. It kept out, and *MON* was the outcome. Now suppose the *EC* government commits itself to a protectionist policy. Knowing that the *US* government's *ex post* choice is free trade, the *EC* firm will expect positive profits and therefore will enter. The outcome will be *PRE*. The *EC* government prefers this to *MON*; the additional payoff ( $PE_1 + PU_2 - K$ ) is exactly the *EC* firm's profit. Therefore, the *EC* government will make the commitment in game 2.

#### B. Entry Deterrence

In games 1 and 2, there are cases where entry occurs but a shift in *US* policy from free trade to protection (holding *EC* policy fixed) makes entry unprofitable. Game 3 has a structure allowing the *US* government to commit to protection and thus deter entry in these cases. It is not always optimal for the *US* government to make such a commitment. It does so if and only if the *MON* achieved by entry deterrence is better for the *US* than the *FTD* or *PRE* which occurs in games 1 or 2. Note that *MON* is preferred by the *US* whenever the producer gains from eliminating a competitor at home and perhaps also abroad outweigh the consumers' surplus lost in the *US* market.

From the point of view of world welfare, there is some presumption that aggressive entry deterrence which shifts the outcome from *FTD* to *MON* is undesirable, as discussed in Section III. A shift from *PRE* to *MON* is desirable provided inequality (6) does not hold. Certainly, whenever entry

promotion is bad, entry deterrence which reverses the outcome is good.

*Example:* (Entry deterrence which counters entry promotion): Return to cell (1,4) and consider game 3. If the *US* government commits itself to protection, then any later *EC* moves to promote entry through protection will fail for want of access to the *US* market. Therefore such moves will not be made and the *US* commitment will produce *MON*. The *US* prefers this to *PRE* and makes the commitment when

$$SU_1 + PU_1 + PE_1 > SU_2 + PU_2,$$

that is, the monopoly profits in the *EC* market outweigh the *US* domestic preference for free trade.

*Example:* (Aggressive entry deterrence): Consider cell (3,4), game 3. By denying access the *US* government can aggressively prevent unassisted entry and achieve *MON* rather than *FTD*, if the *EC* market offers sufficiently higher profits. Our presumption is that such conduct lowers world welfare.

#### C. Dissuasion

It is possible that a commitment by the *US* government to free trade can forestall entry promotion by making it unnecessary for the *EC* to use protection to promote entry. Game 3 has a structure allowing such a commitment, which we refer to as "dissuasion." Since dissuasion always converts *AUT* to *FTD*, it clearly increases world surplus. In fact, it makes both governments better off, as the following example—the only case of dissuasion in Table 3—shows:

*Example:* Consider cell (4,3). Since access in game 2 is unavailable given the *US* domestic preference for protection, the *EC* government goes against its domestic preference and promotes entry via protection. The *US* can avoid this in game 3 by going against its domestic preference and committing to free trade. It prefers the resulting *FTD* to

*AUT* if

$$SU_2 + PU_2 + PE_2 > SU_1 + PU_1,$$

that is, the duopoly profits in the *EC* market are large enough to override the *US* domestic preference. Then it will provide the commitment and the result will be good for both governments.

#### D. Threats and Promises

When a matching strategy in game 4 results in an outcome different from game 3, the changed outcome is the result of a threat or a promise. In a promise, the *US* government changes its policy from protection to free trade in order to get the *EC* government to change its policy as well. In the actual outcome from a threat, the *US* policy does not change (because it is already free trade) but the *EC* is induced to change its policy from protection to free trade. Clearly, threats and promises always lead to *FTD* when they change the outcome of game 3. While the *US* is better off as a result of the availability of threats and promises, the *EC* is made better off by promises, worse off by threats. Both threats and promises, however, always increase world surplus.

*Example (Promise):* Consider cell (4,1). Both governments have a domestic preference for protection, and this suffices for the *EC* firm's entry, producing *AUT*. The *US* would not want to commit unconditionally to free trade; that would only produce *PRE*. But suppose it makes a conditional commitment promising to reciprocate an *EC* choice of free trade. Now the *EC* has another route to entry, namely mutual free trade that provides access. If the *EC* prefers *FTD* to *AUT*, it will pursue this. If, in turn, the *US* prefers *FTD* to *AUT*, it will make such a promise. Such joint preference for *FTD* over *AUT* is possible despite the domestic preferences for protection, if the duopoly profits in each other's market are large enough. Here, a conditional policy overcomes a prisoner's dilemma, allowing the noncooperative outcome

to be replaced by a cooperative outcome preferred by both governments.

*Example (Threat):* Consider cell (4,2). A *US* threat of protecting its own market in response to *EC* protection can lead the *EC* to opt for *FTD* over *AUT*. If the *US* prefers this to the outcome *PRE* of following its domestic preference, it will utilize such a threat. The *EC* is worse off, but world surplus is increased because an additional market is served by both firms.

The above examples illustrate that strategic trade policies work in a variety of ways when applied in different circumstances. Do the various cases suggest any per se rules that a body like GATT would want to adopt concerning such policies? Certainly threats, promises, and dissuasion—all of which lead to *FTD*—should be allowed, and entry promotion which leads to *AUT* should be disallowed. Under the presumption that entry is desirable if and only if all markets are served, a rule mandating bilateral free trade achieves the best outcome possible without subsidies or bargains with the monopolist. Such a rule eliminates all entry promotion as well as aggressive entry deterrence. In the absence of such a presumption, however, no obvious rule emerges.

## V. Strategic Use of Subsidies

Now we allow the *EC* government the additional policy instrument of paying the *EC* firm's sunk cost  $K$ . This increases the number of *EC* policy choices from two to four: "subsidized protection," "unsubsidized protection," "subsidized free trade," and "unsubsidized free trade." If the *EC* chooses to subsidize, the firm will enter irrespective of trade policies.<sup>11</sup> The *US* government can choose its trade policy to affect the *EC* decision in this respect. Countervailing duties are an instance. Both governments also use trade

policies for familiar reasons of domestic preference.

Define games 5–7 as the respective modifications of games 2–4. In game 5, the *EC* government moves first to choose its trade and subsidy policies. In game 6 the *US* government moves first to choose its trade policy. In game 7 it chooses a policy rule contingent on the second stage trade and subsidy choices of the *EC* government. "Matching" is now defined as free trade if the *EC* government chooses unsubsidized free trade, and protection otherwise.

The most interesting cases to consider are those where the *EC* government's domestically preferred policy is free trade. Table 4 shows these cases, which correspond to the last two columns of Table 3. A fifth row has been added to handle the case where sunk costs are so high that entry is unprofitable regardless of trade policies. This case is uninteresting in the absence of subsidies, but must now be considered. Game 7 is not shown separately because its outcome in each of these cases is the same as that of game 6, that is, conditional policies do not give the *US* any additional leverage when the *EC* is able to subsidize.

### A. Entry Promotion

Now use Tables 3 and 4 to compare the outcomes of games 5 and 2. Because the *EC* government's domestically preferred policy is free trade, subsidized free trade is a better instrument for entry promotion than unsubsidized protection. This results in two kinds of changes in outcomes, depending upon whether entry occurs in game 2. When entry does occur in game 2, the *EC* government changes its policy to subsidized free trade in game 5 and thus improves the outcome for both countries. The *EC* is better off because its domestically preferred policy is free trade, the *US* because the *EC* market is opened. The outcome changes from *PRE* to *FTD* or from *AUT* to *USP*, depending upon whether the *US* market is open or closed. In cases where entry does not occur in game 2, the *EC* government sometimes promotes entry with subsidized free trade in game 5. This shifts the outcome from *MON* to *USP* or

<sup>11</sup>The binary choice of paying  $K$  or 0 does not impose any restrictions since any payment in excess of what is needed to induce entry, or short of this level, is a transfer that cancels out in the *EC* government's payoff.

TABLE 4—OUTCOMES OF SUBSIDY GAMES

Conditions for Profitable Entry	Domestically Preferred Policies	
	US Protection EC Free Trade	US Free Trade EC Free Trade
Protection and Access	5. $\text{Max}_{EC}(MON, USP)$ 6. $\text{Max}_{EC}(MON, USP)$	5. $FTD$ 6. $\text{Max}_{US}(FTD, \text{Max}_{EC}(MON, USP))$
Protection	5. $USP$ 6. $USP$	5. $FTD$ 6. $FTD$
Access	5. $\text{Max}_{EC}(MON, USP)$ 6. $\text{Max}_{EC}(MON, USP)$	5. $FTD$ 6. $\text{Max}_{US}(FTD, \text{Max}_{EC}(MON, USP))$
Protection or Access	5. $USP$ 6. $USP$	5. $FTD$ 6. $FTD$
Entry Never Profitable	5. $\text{Max}_{EC}(MON, USP)$ 6. $\text{Max}_{EC}(MON, USP)$	5. $\text{Max}_{EC}(MON, FTD)$ 6. $\text{Max}_{US}(\text{Max}_{EC}(MON, FTD), \text{Max}_{EC}(MON, USP))$

Note: The order of play:

5. Entry Promotion: The EC government chooses its trade and subsidy policies first, then the EC firm makes its entry decision, and finally the US government chooses its (domestically preferred) trade policy.

6. Entry Deterrence: The US government chooses its trade policy (or policy rule contingent on the EC choice) first, then the EC government chooses its trade and subsidy policies, and finally the EC firm makes its entry decision.

*FTD*, again depending upon *US* trade policy. World surplus increases provided inequality (5) or (7) holds. Examples of both kinds of outcome changes are the following:

*Example:* (Entry in both games 2 and 5): Consider cell (1,2) in Table 4, which corresponds to cell (1,4) in Table 3. Without subsidies, entry worked through protection and led to *PRE* in game 2. With subsidized free trade the EC government can pursue free trade and achieve *FTD* in game 5; it prefers this given its domestic preference.

*Example:* (No entry in game 2, entry in game 5): Suppose sunk costs are so high that unsubsidized entry is never profitable, even with both protection and access. This seems a possibility in the Airbus example. When a subsidy is allowed, the EC can promote subsidized entry. The US always responds with its domestically preferred policy, and the resulting outcome—*FTD* or *USP*—is preferred by the EC government if duopoly consumer surplus is large enough relative monopoly consumer surplus.

### B. Entry Deterrence

Now compare games 5 and 6. From Table 4, we see that subsidies are largely immune to commitments, threats, and promises aimed at deterrence by the US. Deterrence only works when the US, by committing to protection and depriving the EC firm of duopoly profits in the US market, makes subsidized entry unattractive for the EC. Since such deterrence shifts the outcome from *FTD* to *MON*, it is undesirable provided inequality (5) holds.

*Example:* (Entry in game 5, deterrence in game 6): Return to cell (1,2) in Table 4. The EC chooses subsidized free trade in game 5, and the outcome is *FTD*. In game 6, if the US chooses protection (or in game 7, matching), it leaves the EC government the choice between no subsidized entry (*MON*) and subsidized entry (*USP*). This can go either way, since  $SE_2 > SE_1$  counteracts  $K > PE_2$ . If the choice is *USP*, the US government is better off with *FTD* and so does not make the commitment. But if the choice is *MON*,

it is possible that the *US* government, preferring this to *FTD*, will commit itself.

If the *EC* government's domestically preferred policy is protection, then subsidies do not affect the outcome, except for the following single case:

*Example:* Consider cell (3,2) of Table 3 and see how game 4 works. The *US* can make a commitment to free trade, protection, or matching. The first draws a protectionist *EC* response, and leads to *PRE*. The second removes access and makes protectionist entry-promotion impossible, so the *EC* government follows free trade and accepts *MON*. The third likewise induces the *EC* government to follow free trade and yields *FTD*. The *US* then picks the best of *MON*, *PRE*, and *FTD*. But it clearly prefers *FTD* over *PRE*, leaving a choice between *FTD* and *MON*. Now introduce subsidies, that is, consider game 7. The *EC* government can respond to *US* protection or matching with a policy of subsidy and protection, achieving *AUT*. This is worse for it than *MON*, so the response to protection is unchanged. But it may be better than *FTD*, so the response to matching may change. In that case the *US* no longer has *FTD* available, and since it prefers *MON* to *AUT*, it is left choosing between *MON* and *PRE*. The formal description of the outcome is

$$\text{Max}_{US}(\text{PRE}, \text{MON}, \text{Max}_{EC}(\text{AUT}, \text{FTD})).$$

In effect, we have the possibility that *FTD* is replaced by *PRE*, a change that is harmful to world welfare.

The discussion in this section suggests that, on balance, subsidies are attractive from the *EC*'s viewpoint. They result in greater gains for the *EC* when utilized and they are more difficult for the *US* to deter. From the point of view of world welfare, they are desirable to the extent that they open the *EC* market but undesirable in a few cases where they promote socially suboptimal new entry. On balance, perhaps, they do more good than harm.

## VI. Modifications and Extensions

We conclude the paper by indicating several ways in which the special assumptions of the model can be altered or relaxed. In most cases, the approach we have developed remains valid, but the taxonomy grows even more complex. We do not think it worthwhile to develop an exhaustive catalogue, but in each instance some cases with special claim to realism would be worth pursuing.

1) *Positive Theory of Policy.* We have taken each government's objective to be the sum of its domestic consumers' and producers' surpluses. This can be changed to a weighted sum to reflect distributive concerns; the categories of domestically preferred policies will then depend on the weights.

The case where consumers' surpluses get zero weights deserves special attention, as it reflects the view that policymakers are captives of concentrated producer lobbies. This can be seen as a positive theory of policy as opposed to our normative approach. Formally, it can be handled as a special case of our model. With all consumers' surpluses set to zero, both governments' domestically preferred policy is protection. The first column of Table 3 then shows that *strategic* use of protectionist policies for entry is irrelevant. The only possible exception (game 4 of the bottom cell) also makes no difference: it is not possible for both governments to prefer *FTD* when only profits count, so the outcome is *AUT*.

2) *Unequal Costs.* If the two firms have unequal costs, we cannot specify monopoly or duopoly profits or consumers' surpluses independently of which firm is involved. This increases the number of cases and makes comparisons more complex. A possible use of this generalization will be to shed light on new investments in declining industries. Dynamic games of *R&D* will also involve unequal costs.

3) *More Incumbents.* When there are two or more incumbent *US* firms, protection in the *EC* will replace this oligopoly by an *EC* monopoly, thus reducing consumers'

surplus. This will bias the *EC* domestic preference toward free trade, and reduce the attractiveness of protected entry.

4) *Third Markets*. If we introduce other markets in nonproducing third countries, we add the appropriate monopoly or duopoly profits to the payoffs. This increases the desirability of entry to the *EC*, but for given *K* makes active promotion less necessary. It also increases the desirability of entry deterrence to the *US*, but makes policies towards this aim less effective.

5) *Resales*. We assumed that the two markets were separate, that is, that price discrimination could be maintained without fear of arbitrage through resale by third parties. The structure of international marketing and managerial practices of buyers of products like aircraft make this assumption fairly realistic. It is also common in the literature on oligopolistic trade. However, if we relax it, we have to change the payoffs in the outcomes *MON* and *FTD*, by calculating profits and surpluses in a world monopoly and duopoly with uniform prices. In the other cases, protection effectively separates the markets. Again, the comparisons and classifications become more complicated.

6) *Variable Tariff Rates*. We have allowed only a discrete choice between zero and prohibitive tariffs. If a continuous range of tariff policies is introduced, each country's domestic preference will generate an optimum tariff for the familiar reasons of rent extraction in oligopolistic trade. Strategic considerations of entry will then hinge on: (i) whether profitable entry is consistent with the two countries' domestically optimum tariffs, (ii) whether a higher *EC* tariff can induce entry, (iii) whether a *US* threat of raising its tariff can deter entry promotion, or a promise of lowering its tariff can dissuade it. The principles of the analysis are unchanged, but the details are more complex, and the calculations will have to postulate a particular solution concept for the duopoly.

7) *Access Charges*. The outcomes of the games we have considered do not generally maximize world-social-surplus. First-best world-social-surplus is not maximized be-

cause governments cannot strike bargains with the incumbent monopolist to supply quantities demanded at marginal cost. Second-best world-social-surplus is not maximized because governments cannot strike bargains with the incumbent monopolist or the entrant about access to domestic markets at all. If governments were able to "sell access" to domestic markets to foreign firms for lump sum amounts, presumably much inefficient protectionism would be eliminated. Furthermore, given that foreign firms cannot buy their way into domestic markets directly, they have an incentive to do so indirectly by setting up domestic subsidiaries and transferring enough monopoly rents to these domestic subsidiaries to make a protectionist policy which destroys these rents undesirable. This would tend to overcome some of the nonoptimality of our outcomes.

8) *Repetitions*. We have considered a single occasion where the opportunity for entry arises. If the governments are engaged in such games repeatedly, with the roles of incumbent and entrant falling to different countries on different occasion, then there would be prospects of cooperation by forswearing protection and achieving *FTD* or *MON*, whichever is better.

# A Framework for Evaluating the Effects of Economic Growth and Transfers on Poverty

By PETER GOTTSCHALK AND SHELDON DANZIGER\*

While the reduction of poverty is a non-controversial policy goal, there is little agreement as to the relative impacts of changes in market and transfer income on poverty. The War on Poverty was predicated on the assumption that increased market incomes resulting from economic growth were not sufficient for alleviating poverty. As the U.S. Council of Economic Advisers stated:

Rising productivity and earnings, improved education, and the structure of social security have permitted many families or their children to escape; but they have left behind many families who have one or more special handicaps. These facts suggest that in the future economic growth alone will provide relatively few escapes from poverty. Policy will have to be more sharply focused on the handicaps that deny the poor fair access to the expanding incomes of a growing economy.

[1964, p. 72]

This view has recently been challenged in public policy debates. According to a recent analysis by the U.S. Office of Management and Budget:

History teaches us that economic growth is a critical determinant of individual and family well-being. In the

decade of the 1970s, the economy failed to perform as well as in the 1960s.... As a result, it was in the 1960s rather than in the 1970s that the greater inroads against poverty were made.

[1983, pp. 30-31]

How sensitive is the incidence of poverty to increased economic activity? One would think that the experience of the last twenty years would offer an almost-ideal social experiment to determine the relative importance of growth in market incomes and income transfers. That economic growth reduces poverty is suggested by the fact that rapid growth during the late 1960's, followed by periods of stagnation and recession, was mirrored by a sharp decline, then a leveling, and then an increase in poverty rates. However, during the period when poverty decreased most quickly, there was also rapid growth in the benefit levels and numbers of recipients of income transfer programs. Furthermore, the recent increase in poverty coincides with reductions in the rate of growth of transfers. In addition, inequality of market income has been increasing since the late 1960's. It is, therefore, impossible to use simple bivariate relationships to account for the sources of changes in poverty.

Most recent attempts (for example, James R. Thornton et al., 1978) to measure the relative importance of growth in market and transfer incomes are in the tradition of W. H. Locke Anderson (1964), Lowell Gallaway (1965, 1967) and Henry Aaron (1967). These studies estimate time-series regressions to obtain the partial effects of economic growth and transfer programs on poverty. Elsewhere, we have shown (1983) that the conflicting conclusions of these studies can be attributed to the time-series data which are too highly collinear to yield robust co-efficient estimates. Minor changes in func-

tional form or variable measures substantially change the relative importance of market and transfer incomes.

In this paper, we develop an alternative framework for measuring the relative effects on poverty of growth in mean market income, mean transfer income, and inequality. We analyze the relationship between changes in the location and shape of the joint distribution of various income sources (i.e., the mean and higher level moments of market and transfer incomes) and a summary measure of inequality (in this case, poverty). The technique is general and could equally well be applied to other breakdowns of income (for example, husband's and wife's earnings) or other summary measures (for example, quintile shares).

Section I develops the conceptual framework, which is used in Section II to decompose the sources of the decrease in poverty between 1967 and 1979 and the subsequent rise in poverty between 1979 and 1982.

### I. Conceptual Framework

We begin by defining changes in poverty in terms of changes in the underlying distribution of income. Let the poverty rate be defined as

$$(1) \quad P = \int_{-\infty}^T \int_{-\infty}^{T-I_2} g(I_1, I_2, \mathbf{m}) dI_1 dI_2,$$

where  $I_1$  and  $I_2$  are two sources of income (in this case, market and transfer incomes),  $T$  is a poverty threshold, and  $g$  is the joint density function of  $I_1$  and  $I_2$ , which is defined in terms of a vector of parameters,  $\mathbf{m}$ .

Writing the total differential of  $P$  with respect to its  $k$  parameters,

$$(2) \quad dP = \sum_{i=1}^k (\partial P / \partial m_i) dm_i,$$

allows us to decompose the total change in poverty into changes due to each of the  $k$  parameters. Changes in these parameters in turn reflect changes in the moments of the distribution.

To determine the relative effects of observed changes in all the moments of the

distribution on poverty, we must specify a particular functional form for  $g$ . Our distributional assumption is guided by two principles: the function should not be more restrictive than functional forms applied elsewhere in the income distribution literature; and the form should depend on a sufficiently small number of parameters to make empirical work tractable. The displaced lognormal distribution meets these criteria. This three-parameter distribution is more general than the better known two-parameter lognormal distribution. It also corrects for the negative skewness found in the distribution of log income.

Because the official poverty thresholds vary by family size, the bound of integration in equation (1) cannot be treated as a fixed number. To avoid excessive complexity, we divide each household's income by its poverty threshold and define the income-to-needs ratio as

$$(3) \quad I^* = (I_1 + I_2)/T.$$

Any household with an income-to-needs ratio below one is poor.<sup>1</sup>

We assume that  $I^*$  has a displaced lognormal distribution, an assumption supported by a Kolmogorov-Smirnov test (Morris DeGroot, 1975).<sup>2</sup> Therefore,

$$(4) \quad Z = [\ln(I^* + c) - \mu] / \sigma,$$

<sup>1</sup>An alternative solution to dividing income by the poverty line would be to expand the conceptual framework to take account of changes in the trivariate distribution of household needs, market incomes, and transfers. Poverty would then depend on four additional moments (the mean and variance of needs as well as the covariances of needs with market incomes and transfers). While our formulation is less general and requires that we make distributional assumptions about income-to-needs ratios, rather than income alone, it keeps data problems manageable. An examination of the data indicates that the assumption of displaced lognormality was as applicable to income-to-needs as to income.

<sup>2</sup>Since we model changes in poverty in terms of changes in the cumulative distribution below the poverty line, we are concerned with the shape of the distribution at  $I^* = 1.0$ . We performed Kolmogorov-Smirnov tests to see whether we could reject the hypothesis that the income-to-needs distributions were lognormal. Using 1967 and 1982 data on all persons and for persons living

which has a standardized normal distribution with density function  $\phi(Z)$ .<sup>3</sup> The three parameters of this distribution are  $\mu$ ,  $\sigma^2$ , and  $c$ , the displacement factor (John Aitchison and J. A. C. Brown, 1957). Changes in  $c$  reflect the partial effects of changes in the third moment about the mean. The first two parameters are themselves the first two moments of the distribution of  $\ln(I^* + c)$  since

$$(5) \quad \mu = E[\ln(I^* + c)];$$

$$(6) \quad \sigma^2 = \text{var}[\ln(I^* + c)].$$

Since poverty is defined as an income-to-needs ratio less than one, we can write

$$(7) \quad P = \int_{-\infty}^h \phi(z) dz,$$

$$\text{where } h = [\ln(1.0 + c) - \mu] / \sigma.$$

Poverty is, therefore, a function only of the parameters of the distribution of  $\ln(I^* + c)$ .

For ease of interpretation, we use the following results from Charles Metcalf (1972) to define the distribution in terms of  $c$  and the mean ( $\alpha$ ) and variance ( $\beta^2$ ) of  $I^*$ , rather

than the mean and variance of  $\ln(I^* + c)$ :

$$(8) \quad \mu = \ln \left\{ \frac{(\alpha + c)^2}{[\beta^2 + (\alpha + c)^2]^{1/2}} \right\};$$

$$(9) \quad \sigma^2 = \ln \left\{ \frac{[\beta^2 + (\alpha + c)^2]}{(\alpha + c)^2} \right\}.$$

We can, therefore, decompose changes in poverty into three components:

$$(10) \quad dP = (\partial P / \partial \alpha) d\alpha + (\partial P / \partial \beta^2) d\beta^2 + (\partial P / \partial c) dc.$$

This decomposition can be further expanded by recognizing that

$$(11) \quad \alpha = E(I^*) = E(I_1^*) + E(I_2^*);$$

$$(12) \quad \beta^2 = \text{var}(I^*) = \text{var}(I_1^*) + 2\text{cov}(I_1^* I_2^*) + \text{var}(I_2^*),$$

where asterisks again indicate income as a proportion of needs. Therefore,

$$(13) \quad dP = \frac{\partial P}{\partial \alpha} dE(I_1^*) + \frac{\partial P}{\partial \alpha} dE(I_2^*) + \frac{\partial P}{\partial \beta^2} d\text{var}(I_1^*) + 2 \frac{\partial P}{\partial \beta^2} d\text{cov}(I_1^* I_2^*) + \frac{\partial P}{\partial \beta^2} d\text{var}(I_2^*) + \frac{\partial P}{\partial c} dc.$$

Equation (13) shows how the total change in poverty,  $dP$ , can be decomposed into changes in poverty associated with changes in means, the dispersion of each income source, their covariance, and the displacement factor.

Given our distributional assumption, we can derive explicit expressions for the partial derivatives in equation (13):<sup>4</sup>

$$(14) \quad \frac{\partial P}{\partial \alpha} = \frac{\phi(h)}{\sigma^2(\alpha + c)[\beta^2 + (\alpha + c)^2]} \times \{ h\beta^2 - \sigma[2\beta^2 + (\alpha + c)^2] \};$$

<sup>4</sup>The derivation is given in the Appendix.

in households headed by prime-aged men, we tested the hypothesis between the tenth and the fifteenth percentiles for all persons and between the fifth and tenth for men, since these portions of the distribution include all the observed poverty levels for the two groups over the 1967-82 period.

Since the Kolmogorov-Smirnov test is based on the maximum difference between the cumulative empirical and theoretical distributions, large deviations outside the area of interest will lead to the rejection of displaced lognormality for the full distribution. This was in fact the case. However, in the specified ranges, we could not reject at the 5 percent level the hypothesis that the four distributions we tested were lognormal. For example, in 1982, the maximum difference between the two cumulative distributions for prime-age men between the tenth and the fifteenth percentiles was .0025, where the actual value was .0501 and the theoretical value was .0475 percent.

<sup>3</sup>Because we assume that  $I^*$  follows a displaced lognormal distribution, the distribution of market income-to-needs and that of transfer income-to-needs cannot each follow a displaced lognormal—the sum of two displaced lognormals is not itself displaced lognormal. In fact, the empirical distribution of transfers-to-needs is clearly not lognormal.

$$(15) \quad \frac{\partial P}{\partial \beta^2} = \frac{\phi(h)}{2\sigma^2[\beta^2 + (\alpha + c)^2]}[\sigma - h];$$

$$(16) \quad \frac{\partial P}{\partial c} = \frac{\phi(h)}{(1+c)\sigma} + \frac{\partial P}{\partial \alpha}.$$

With time-series data on the displacement factor and the means, variances, and covariance of  $I_1^*$  and  $I_2^*$ , we can use equation (13) and the three partial derivatives in equations (14)–(16) to decompose changes in poverty. The differentials in equation (13) are approximated by finite changes in each parameter. The partial derivatives, which are solely functions of  $\alpha$ ,  $\beta^2$ , and  $c$ , are evaluated at the average values for these parameters for each pair of years.

The methodology developed here differs from that of the time-series regression studies cited earlier. Those studies have looked only at changes in the first moments of the distribution and assumed that the relationship was linear, implying that the derivatives of poverty with respect to the first moments are each constant and that the derivatives with respect to all higher level moments are zero. These unrealistic assumptions, in addition to data problems, cast doubts on the methodology as well as the results of prior studies.

In the following section, we apply our methodology to determine the impacts of growth in market and transfer income on poverty during the period 1967 to 1982.

## II. Empirical Results

The annual March *Current Population Surveys* (CPS) for 1968 through 1983, each of which contains information on about 50,000 households (U.S. Department of Commerce, 1968–83), were used to calculate sample means, variances, and covariance of  $I_1^*$ , which we define as market income (wages, salaries, self-employment income, dividends, interest, rents, private pensions, etc.) measured as a proportion of needs, and  $I_2^*$ , cash government transfers (social insurance and public assistance) measured as a proportion

of needs.<sup>5</sup> This sample information is used to calculate estimates of  $\alpha$  and  $\beta^2$ .

An additional piece of information is needed to estimate  $c$ . Metcalf (p. 21) uses the relationship between  $\alpha$  and the 10 percent and 90 percent cutoffs for that estimation. We follow a similar method. Since we are primarily interested in the shape of the distribution near the poverty cutoff (where  $I^*$  equals one), we use a method which insures that the distribution based on  $\hat{\alpha}$ ,  $\hat{\beta}^2$ , and  $\hat{c}$  yields an estimated cumulative density which is equal to the observed cumulative density at the cutoff.

Let  $h$  be the standardized normal variate, defined in equation (7), which is consistent with the observed poverty rate. Equations (7), (8), and (9) are, therefore, three nonlinear equations in three unknowns— $\hat{\mu}$ ,  $\hat{\sigma}$ , and  $\hat{c}$ —which can be solved from three observed quantities— $\hat{h}$ ,  $\hat{\alpha}$ , and  $\hat{\beta}^2$ . These equations are solved numerically in each year to yield estimates of  $c$ .

The means, variances, covariance, and displacement factor are shown in columns (1)–(6) of Table 1. We use these data to calculate the partial derivatives in each year, shown in columns (7)–(9).<sup>6</sup> The decline in the derivatives of poverty with respect to mean market or mean transfer income in all but recessionary years shows that declining antipoverty effectiveness of growth as the density at the poverty line decreases.

<sup>5</sup>We would prefer to include the value of in-kind market income (for example, fringe benefits) and transfers in our poverty measure. Unfortunately, CPS data tapes that include in-kind transfers are available only for a few years. Since these transfers have been growing, their inclusion would increase the relative antipoverty effects of growth in transfers compared to growth in market income.

We use the terms market income and transfer income interchangeably with the more cumbersome terms market income-to-needs ratio and transfer income-to-needs ratio.

<sup>6</sup>Because changes in the moments of the distribution change the values of the partial derivatives, the derivatives shown in Table 1 are evaluated at the average values of the moments between adjacent years. For example, the 1982 value of  $-0.178$  for the derivative with respect to the means,  $\partial P / \partial \alpha$ , reflects the impact of a unit change in  $\alpha$ , evaluated at the average 1981–82 values of  $\alpha$ ,  $\beta^2$ , and  $c$ .

TABLE 1—MOMENTS, DISPLACEMENT FACTORS, PARTIAL DERIVATIVES, AND POVERTY RATES FOR ALL PERSONS 1967–82

	Mean		Variance		Covariance of Market Income and Transfers	Displace- ment Factor	Partial Derivatives with Respect <sup>a</sup> to			Official Poverty Rate

Source: Computations by authors from March *Current Population Surveys*. Zero and negative incomes are included in calculating the moments.

<sup>a</sup>The derivative is applicable to the change in the moments from the previous the indicated year.

The data in Table 1 give the basic information necessary to decompose changes in poverty. For example, from 1981 to 1982 mean market income and mean transfers (each measured as a proportion of needs) changed by  $-0.023$  and  $0.018$ , respectively. Adding these two components of mean income and multiplying the sum by  $-0.178$  ( $\partial P/\partial \alpha$ , shown in col. (7)) shows that changes in the mean of the income/needs distribution (the first two terms in equation (13)) increased poverty by .0009 (i.e., .09 percentage points). This is less than one-tenth of the total one-point rise in the poverty rate over the two years. The impact of changes in the variances, covariance, and displacement factor on poverty are obtained by repeating the calculations for the other terms in equation (13). When all of these terms are summed, they equal the 1.0 point increase in poverty, shown in column (10).

The computations using the data in Table 1 are summarized in Table 2. We aggregate across time periods and sources of change in

poverty. Since 1979 is the last nonrecessionary year, we examine changes in poverty over the subperiods 1967 to 1979 and 1979 to 1982.<sup>7</sup> The first period is marked by economic growth, as market income-to-needs increased by 17.4 percent, or about 1.4 percent per year; the second by cyclical decline, as market income-to-needs declined by 7.4 percent, or about 2.5 percent per year. In the first period, transfer income-to-needs increased by 9.8 percent; in the second, by 7.2 percent.

Since there have been major demographic shifts in the population, the data for all persons may reflect changing household composition as well as changes in the income distribution of each demographic group. Therefore, Table 2 also analyzes changes in poverty for persons living in households

<sup>7</sup>The data in Table 1 are used to calculate the partial effects in each year; the data in Table 2 show these effects summed over each subperiod.

<sup>e</sup> Persons in households with male or female head 65 years or older.

headed by young men and prime-aged men, two demographic groups that are expected to benefit most directly from economic growth, and for persons living in households headed by elderly men and women.<sup>8</sup>

Sources of changes in poverty are aggregated into three groups, in columns (2)-(4) of Table 2. Column (2) shows the impact of changes in mean market income, holding the

coefficient of variation and the coefficient of skewness of market income constant. It can, therefore, be interpreted as the effect of changes in the mean, holding relative inequality constant.<sup>9</sup> Column (3) shows the

<sup>8</sup> Unfortunately, we cannot decompose changes in poverty for persons living in households headed by nonaged women or black men and women. Our method of estimating the displacement factor requires the existence of a value consistent with the observed poverty rate and the mean and variance of the group-specific income-to-needs distribution. No such values exist for households headed by nonaged women or blacks, even when they are disaggregated into four age-race cells. The fact that the displaced lognormal distribution fits well at the poverty line for all persons and all men (see fn. 2), but does not provide a good approximation for women or blacks, suggests further research using alternative distributional assumptions.

<sup>9</sup> We begin with initial-year values for the means and the second- and third-level moments of each demographic group (including the covariances and corresponding third-level cross products). We then assume that each household's market and transfer income-to-needs ratios grew at the same rates as the observed increases in the means of the two income sources and calculate values of the second- and third-level moments consistent with these proportional growth rates. This ensures that the coefficient of variation and coefficient of skewness of each income source remain constant. Note that total income inequality will change when each income source grows proportionally unless each grows at the same rate.

Poverty rates consistent with proportional growth in market income are in col. (2) of Table 2. Col. (3) shows the net poverty reduction that results when transfers grow at their observed rate. Col. (4) shows the impact of changes in the shape of the distribution due to the

corresponding impact on changes in mean transfer income. The last column shows the impact of the remaining factors which change the shape of the distribution. This grouping reflects our interest in the relative effects on poverty exerted by economic growth, transfer growth, and changes in inequality.<sup>10</sup>

Row 1 of Table 2 shows that the official poverty rate for all persons declined by 2.6 percentage points between 1967 and 1979. Column (2) shows the effect of increases in the mean of market income (holding the shape of the distribution constant). This reflects the poverty-reducing effects of increases in mean market income and the poverty-increasing effects of increases in the variance, and the effects of changes in the covariance and displacement factor, all resulting from proportional growth in the market income of each household. The net effect was a decline in poverty of 3.3 percentage points. Increases in mean transfers decreased poverty by an additional 3.5 points. Growth in mean transfer income was, therefore, slightly more important than that of mean market income in reducing poverty over this period.

These two poverty-reducing factors were partially offset by changes in the shape of the distribution, which increased poverty by 4.2 points. Increased inequality was more important than growth in the mean of either income source. Thus, a substantial portion of the antipoverty impact of economic growth was canceled by rising inequality.

---

deviations of the variance, covariance and displacement factor from the values consistent with proportional growth in each household's market and transfer income. The data in col. (4) are computed as residuals, i.e., as the actual values in col. (1) less the computed values in cols. (2) and (3).

<sup>10</sup>The decomposition of Table 2 proceeds as if transfer growth has no effect on the distribution of market income, and vice versa. However, because of labor supply responses to transfers, some portion of the effect of growth in transfers on poverty is being classified as a change due to the resulting reduction in market incomes. Similarly, since some transfers are income-tested, a portion of the effect of growth in market income on poverty is classified as a change due to the resulting decline in transfer income. A simulation that assumed large behavioral responses (see our earlier paper) did not alter our qualitative conclusions.

Between 1979 and 1982, poverty for all persons increased from 11.7 to 15.0 percent. (The decline in mean market income increased poverty by 0.9 points.) The poverty-reducing impact of growth in mean transfers —0.4 points—was much smaller in this period, because transfers as a percentage of needs grew much more slowly after 1979 than in the previous period. Changes in the shape of the distribution increased poverty by 2.8 points in only three years. This confirms the importance of focusing on the shape as well as the position of the distribution—if each household's market income had decreased by the observed 7.4 percent and the transfer income of each had increased by the observed 7.2 percent, poverty would have risen by only 0.5 points (col. (2) plus (3)), instead of the actual 3.3 point increase.

As expected, the relative importance of changes in mean market incomes is greater for persons living in households headed by young and prime-aged men.<sup>11</sup> The impacts of changes in the shapes of the demographic-specific distributions, shown in column (4), were, however, nearly as important for each of these groups as for all persons. The tendency toward greater inequality is, therefore, not solely a reflection of demographic shifts (also, see Martin Dooley and Gottschalk, 1984). Note that the 1979–82 downturn in mean market income and the increased inequality more than offset the observed declines in poverty between 1967 and 1979 for these groups.

The largest drop in poverty between 1967 and 1979 (14.7 points) and the only decline between 1979 and 1982 occurred for households headed by elderly persons (men and women). As might be expected, this decline was almost solely a result of growth in mean transfers, primarily Social Security benefits.

<sup>11</sup>While we focus on the impact of changes in the *group-specific* moments on each group's poverty rate, our methodology could be expanded to reflect the impact of changes in the moments of the *aggregate* distribution on group-specific poverty rates. One would need to estimate the sensitivity of the group-specific moments to changes in the moments of the overall distribution. These elasticities would depend on the source of the change in the overall distribution.

### III. Conclusions

We have developed a framework that shows how changes in the poverty rate result from changes in the location and shape of the income distribution. By assuming that the income-to-needs ratio follows a displaced lognormal distribution, we are able to quantify the relative importance of changes in mean market incomes, mean transfers, and inequality. During the 1967-79 period, changes in transfers were about as important as increases in market incomes for all persons. Transfers were less important for non-aged men, and very important for elderly. Since 1979, the decline in market incomes has increased poverty, and the antipoverty effect of transfer growth has declined. Rising inequality increased poverty for all persons and for each group analyzed during the period of growth as well as during the recent recessionary period.

### APPENDIX

The derivatives of poverty with respect to  $\alpha$ ,  $\beta^2$ , and  $c$  can be obtained by recognizing that

$$(A1) \quad \frac{\partial P}{\partial \alpha} = \frac{\partial P}{\partial h} \left[ \frac{\partial h}{\partial \mu} \frac{\partial \mu}{\partial \alpha} + \frac{\partial h}{\partial \sigma^2} \frac{\partial \sigma^2}{\partial \alpha} \right];$$

$$(A2) \quad \frac{\partial P}{\partial \beta^2} = \frac{\partial P}{\partial h} \left[ \frac{\partial h}{\partial \mu} \frac{\partial \mu}{\partial \beta^2} + \frac{\partial h}{\partial \sigma^2} \frac{\partial \sigma^2}{\partial \beta^2} \right].$$

Each component of equations (A1) and (A2) can be obtained from equations (7) to (9) in the main part of the text. Differentiating equation (7) yields

$$(A3) \quad \partial P / \partial h = \phi(h),$$

$$(A4) \quad \partial h / \partial \mu = -1/\sigma,$$

$$(A5) \quad \partial h / \partial \sigma^2 = -h/2\sigma^2.$$

Differentiating equations (8) and (9) yields

$$(A6) \quad \frac{\partial \mu}{\partial \alpha} = \frac{2\beta^2 + (\alpha + c)^2}{(\alpha + c)[\beta^2 + (\alpha + c)^2]},$$

$$(A7) \quad \frac{\partial \sigma^2}{\partial \alpha} = -\frac{2\beta^2}{(\alpha + c)[\beta^2 + (\alpha + c)^2]},$$

$$(A8) \quad \frac{\partial \mu}{\partial \beta^2} = -\frac{1}{2[\beta^2 + (\alpha + c)^2]},$$

$$(A9) \quad \frac{\partial \sigma^2}{\partial \beta^2} = \frac{1}{\beta^2 + (\alpha + c)^2}.$$

Substituting these expressions into equation (A1) and (A2) yields

$$(A10) \quad \frac{\partial P}{\partial \alpha} = \frac{\phi(h)}{\sigma^2(\alpha + c)[\beta^2 + (\alpha + c)^2]} \times \{h\beta^2 - \sigma[2\beta^2 + (\alpha + c)^2]\},$$

$$(A11) \quad \frac{\partial P}{\partial \beta^2} = \frac{\phi(h)}{2\sigma^2[\beta^2 + (\alpha + c)^2]}[\sigma - h].$$

This shows how poverty changes with the mean and variance of the distribution of  $I^*$ .

The impact of changes in the displacement factor,  $c$ , on poverty can be obtained by recognizing that

$$(A12) \quad \partial h / \partial c = 1/(1 + c)\sigma + \partial h / \partial \alpha.$$

Therefore,

$$(A13) \quad \partial P / \partial c = \phi(h)/(1 + c)\sigma + \partial P / \partial \alpha.$$

# A Theory of Two-Tier Labor Markets in Agrarian Economies

By MUKESH ESWARAN AND ASHOK KOTWAL\*

Economic analysis of agricultural tenancy has yielded rich insights into the institutional mechanisms that evolve as rational responses to the state of market development and production technology. In many respects, the study of tenancy has been a forerunner of the modern literature that is attempting to create a theory of organization based on the analysis of incentive mechanisms underlying the contractual structure. It may be quite fruitful, therefore, to study premodern institutions, especially if they have recurred in diverse environments or at different time periods, and have proved to be historically tenacious. The more anomalous they seem, at first glance, the more rewarding may their analysis prove to us.

One such institution that has not been subjected to economic analysis until recently (Alan Richards, 1979; Pranab Bardhan, 1983) is the institution of permanent workers. Permanent workers (alternatively referred to as tied laborers, estate laborers, farm servants, or attached workers) have existed in agrarian economies as diverse as those of thirteenth-century England, Tokugawa Japan, East Elbian Germany (1750–1860), the Egyptian Delta (1850–1940), pre-1930 Central Chile, and present day India. This institution has exhibited certain common features across different time periods and regions. First, in sharp contrast to the so-called “casual workers” hired on a daily basis, permanent workers are engaged on long-term contracts that span entire crop periods, years, and, sometimes, lifetimes. Second, the employment relationship between the landlords and

these laborers is highly personalized and involves patronage benefits such as homesteads, consumption credit, holiday gifts, and emergency aid in return for total loyalty. A permanent worker is expected to remain loyal to the landlord and further the landlord's interests even in periods of strife between the landlord and casual workers (Sheila Bhalla, 1976; Bardhan and Ashok Rudra, 1981; Richards, 1979). Third, the incidence of this seemingly backward institution appears to increase in response to what may be construed as modernizing stimuli. The opening up of new markets for Chilean agrarian products in the nineteenth century and the consequent increase in labor demand resulted in an increase in the number and proportion of permanent labor contracts (Richards, 1979). Those regions in North India (Haryana) with wider diffusion of new technology and consequently higher labor demand also exhibit greater proportion of permanent labor contracts (Bhalla). A theory of the institution of permanent labor should, therefore, simultaneously explain: (a) why the landlord places such a premium on loyalty, (b) the choice of the instruments he uses to elicit such loyalty, and (c) the increase in the incidences of permanent labor contracts in response to an increase in labor demand.

Bardhan (1983) has recently proposed an explanation for the institution of permanent labor, based on the following idea. Risk-averse workers faced with an uncertain spot wage can engage in long-term contracts with risk-neutral landlords for a prenegotiated wage, albeit at a rate lower than the expected spot rate. Workers, who are assumed to have heterogeneous opportunity incomes, self-select into the permanent and casual labor markets. The main comparative static result of this model explains the well-acknowledged empirical finding that the proportion of permanent workers is higher in tighter la-

\*Department of Economics, University of British Columbia, Vancouver, B.C., V6T 1Y2 Canada. We thank R. Allen, C. Archibald, P. Bardhan, B. C. Eaton, J. Kesselman, T. Lewis, G. MacDonald, M. Manove, P. Neher, P. Tandon, and anonymous referees for helpful comments.

bor markets.<sup>1</sup> In an earlier paper (1979a), Bardhan proposed an alternative explanation for the existence of permanent contracts that was based on differential recruitment costs. Although he noted the importance of the patron-client aspects of the institution of permanent labor, the focus of his two models was to explain the longer duration of the contract. Patron-client aspects, such as loyalty, which are distinctive and inalienable features of the institution of permanent labor, are yet to be formally analyzed.

In this paper we follow the lead of Richards (1979), who has analyzed the institution of permanent labor in the widely different agrarian economies of East Elbian Germany, Egypt, and Chile. His investigation led him to the hypothesis that this institution emerged as a subtle means of supervising labor. A cursory examination of the differences in the tasks assigned to the two kinds of hired labor reveals that important tasks that require judgement, discretion, and care (and are difficult to monitor) are seldom, if ever, assigned to casual workers.<sup>2</sup> Permanent workers, on the other hand, are often entrusted with such responsibilities, almost as if they were family members. Our theory of the institution of permanent labor is based on the hypothesis that it is an attempt by the landlords to transform hired labor into workers whose behavior would approximate that of family labor, thus reducing the burden of on-the-job supervision. Do any of the stylized facts available on the terms of permanent contracts suggest a mechanism that could elicit such behavior from hired workers?

A significant and yet puzzling observation reported by Prafulla Sanghavi (1969) and Bardhan (1979a) is that permanent workers in Indian agriculture typically enjoy a significantly higher annual income (despite a lower daily wage) than casual workers.<sup>3</sup> In addition, permanent workers get consumption loans, homesteads, and other patronage benefits while casual workers face a great deal of uncertainty on the labor markets (Bardhan, 1983; Bhalla). It seems inconceivable that workers close to subsistence and without either employment opportunities or savings could be indifferent between a permanent contract that assures employment and consumption even in slack seasons and a precarious dependence on casual markets. To a worker at subsistence, neither the greater burden of responsibility and more work, nor the distaste for the serf-like existence under the close control of the landlord are reasons compelling enough to render the two types of contracts equivalent in utility.<sup>4</sup> On the other hand, it is equally puzzling that landlords would find it necessary to pay higher-than-opportunity incomes to their permanent workers. It might be natural to presume that the permanent workers are more able and, therefore, earn higher incomes than casual workers. The income differential between the two classes would be explained as ability-rent only if there is no excess supply of able people. In that case, the composition of the labor force would be insensitive to intensification of agriculture, contradicting the observations of Richards (1979).

An explanation of why employers are sometimes found to pay higher-than-oppor-

<sup>1</sup>In addition to Bardhan's own work on East India (1979), this finding has been found to be empirically valid in Chile (pre-1930), East Elbian Germany (1750-1860), and Egypt (1850-1940), as documented in Richards (1979).

<sup>2</sup>See Shigemochi Hirashima (1978, p. 109) for a description of the differential tasks assigned to the two kinds of workers in Pakistan. Also see Thomas Smith (1959) on the tasks performed by permanent workers in Tokugawa Japan and M. M. Postan (1954) for a description of the duties of estate workers in thirteenth-century England.

<sup>3</sup>In Sanghavi (Table 4.7, p. 100), the data on all states in North India, except for Uttar Pradesh, showed a higher annual income for male attached workers by a range of 15-100 percent. Bardhan (1979a) found that the average level of consumption for the family members of permanent workers in Bengal was Rs. 32/month/capita where as it was Rs. 24/month/capita for the family members of casual workers.

<sup>4</sup>For persuasive accounts suggesting that permanent workers are better off than casual workers, see Richards on Egypt (1982, p. 63); Arnold Bauer on Chile (1971, p. 1072).

tunity incomes to their employees has recently been proposed by B. Curtis Eaton and William White (1983). The idea, put simply, is that an income differential maintained over the opportunity income of the worker serves as a monitoring device; any shirking by the worker would invite the threat of getting fired and losing the stream of income differentials.<sup>5</sup> By replacing the income differential with a utility differential and assuming that the opportunity utility of a permanent worker is the expected utility of a casual worker (i.e., assuming an environment with no other employment opportunity), we can adapt the Eaton-White framework to answer the questions we posed earlier. The landlords transform some of the hired laborers into loyal laborers by keeping them at a higher utility level than what they could otherwise attain. The excess demand for permanent jobs thus created is sustained in equilibrium, since it enables the landlords to entrust responsible tasks to an artificially created cadre of loyal workers who would have been prohibitively expensive to supervise otherwise. The wage that minimizes the total labor costs (including wage and supervision costs) is higher than the wage that would minimize the wage costs alone. This framework explains the observation made by Bhalla and Richards (1979) that the permanent workers constitute a class within the class of agricultural workers—the upper tier in an artificially created “two-tiered” labor force. They receive superior benefits and tend to align themselves with their employers under most circumstances. It is important to note, however, that such contracts are viable only if they are long term and if reputation plays an important role so that the fired worker cannot secure another contract soon afterwards.

The above framework is an accurate representation of the institution of permanent labor as described by historians. For example, Arnold Bauer observes that in nine-

teenth-century rural Chile:

Numerically few, the *inquilinos* [permanent workers] were the cream of the rural labour.... This selectivity was made possible by the limited need for estate labour and the lack of alternatives open to the numerous rural families. The good fortune of being accepted on the hacienda was repaid by the *inquilinos* with service and loyalty.

[1975, p. 56]

Our assumption that permanent workers are kept at a higher utility level than casual workers is borne out by the accounts of Richards (1979) on the institution as it prevailed from 1850 to 1940 in Egypt, from 1750 to 1860 in East Elbian Germany, and in pre-1930 Central Chile. Richards also observes: “An Instmann [permanent worker] dismissed for insubordination would quickly find himself among the insecure ranks of *Eigenkatner* and *Einlieger* [casual workers]” (1979, p. 512).

A legitimate question that may be raised at this point is: why doesn't the landlord offer a tenancy contract to the worker? We have explained elsewhere our view that the choice among fixed rental, sharecropping, and fixed wage contracts are influenced by the distribution of certain unmarketed resources across landlords and workers (see our forthcoming article). It is demonstrated there that this, together with the technology and the type of crops, determines the contractual structure that would prevail; even with a linearly homogeneous technology, tenancy contracts will not necessarily obtain. A permanent contract is essentially a wage contract in which the landlord undertakes management and employs a subtle supervision technique that avoids resorting to continuous monitoring, and we model it as such.<sup>6</sup> Such a supervision technique is viable only with long-term contracts since the landlord

<sup>5</sup>A similar idea also appears in Steven Stoft (1980) and, more recently, in Carl Shapiro and Joseph Stiglitz (1984).

<sup>6</sup>Introducing the possibility of tenancy in this model would greatly complicate the formulation, and is a task to be accomplished in future research.

depends on imperfect indicators of the workers' efforts which are gathered almost costlessly as by-products of other management activities. Any meaningful judgment as to whether a worker has been supplying an acceptable level of effort can only be formed after reviewing the accumulated information on the worker's performance over the entire crop season. The landlord is then able to form a judgment on whether or not to fire the worker. For tractability, we shall assume that after the crop has been harvested and counted, the landlord has sufficient information accumulated to know with certainty if the worker has supplied an acceptable level of effort.

To sum up, we postulate that the institution of permanent labor exists in order to facilitate the assignment of important labor tasks to hired labor without having to devote inordinately large amounts of resources to supervision. It enables the landlord to utilize valuable information about the worker's performance that can be costlessly gathered while the landlord is engaged in performing other managerial activities. The permanent worker's income is maintained at a level that renders him a utility sufficiently greater than his opportunity utility that he would choose to supply the acceptable level of effort. Any change in the casual worker's wages, that are determined in a competitive market, results in a corresponding change in the permanent worker's wages.

In Section I, we present a general equilibrium model that incorporates the seasonal nature of agricultural production. The labor market consists of homogeneous workers allocated between permanent and casual workers according to the different tasks assigned. We work out the implications of the model assuming for the workers' utility function a specific form which gives rise to a labor supply function that is consistent with empirical observations. In Section II, we then carry out comparative static exercises and examine the link between the incidence of permanent labor and the different characteristics of the production technology. In the final section, we elaborate on the general

applicability of the essential principle modeled in this paper to discourage morally hazardous behavior.

### I. The Model

We assume that a single crop is produced each year; the crop takes two periods to produce, each period lasting for one-half year. The two periods posited for the production of a crop enable us to capture the variation in the demand for labor and capital over the year. For concreteness, the first period can be viewed as requiring such activities as soil preparation, tilling, sowing, etc., and the second as the period of harvesting, threshing, etc. Typically, the demand for labor and capital is considerably higher in the second period.

We envisage the production process as entailing the use of three inputs: land ( $h$ ), capital ( $K$ ), and labor. It is imperative for our purposes to disaggregate the labor input, and this we do according to the nature of the tasks performed. It is sufficient to consider two broad categories of tasks. Type 1 tasks are those that involve considerable care and judgment (such as water resource management, the application of fertilizers, maintenance of the draft animals and machines, etc.). Such tasks do not lend themselves to easy on-the-job supervision. Type 2 tasks are those that are routine and menial (such as weeding, harvesting, threshing, etc.). Since they involve little discretion, productivity on such tasks can be directly gauged from the extent of the workers' physical activity. In other words, Type 2 tasks are by their very nature easy to monitor. All workers are assumed to have identical abilities. However, even though all workers are drawn from a homogeneous labor force, the tasks to which they are assigned are not necessarily the same.

We draw a distinction between the length of a worker's employment over a period ( $l$ ) and the "intensity" of effort ( $e$ ) with which he applies himself. Efficient performance of a task (either Type 1 or Type 2) requires an effort level  $\bar{e} > 0$ . Since effort is deemed a bad, a worker on a fixed wage will set  $e = 0$

unless he is monitored. We shall take an efficiency unit of labor to be one worker hired for a whole period ( $l=1$ ) at an effort level  $\bar{e}$ . As will be explained below, Type 1 tasks are performed by workers with long-term contracts, while workers hired on the spot market (casual workers) are entrusted with only Type 2 tasks. Empirically, we observe that casual workers are hired mainly in the peak season (i.e., the second period). This is because the tasks to be performed in period 1 are mainly of Type 1 variety—soil preparation, plowing (which entails the use of draft animals or tractors), application of fertilizers, etc. For simplicity we assume that no casual workers are hired in period 1. We let  $L_p$  denote the number of efficiency units of permanent labor employed per period on a typical farm. A permanent worker's contract is over the infinite horizon unless he is found to shirk. We denote by  $L_c$  the number of efficiency units of casual labor employed on the farm in period 2. A casual worker's contract lasts for the whole or part of this period.

We posit that the output,  $q_1$ , of period 1 can be written

$$(1) \quad q_1 = a \min \{ g_1(K_1, L_p), bh \},$$

where  $K_1$  is the amount of capital used in period 1,  $h$  is the amount of land used, and  $a, b > 0$ , and  $g_1(K_1, L_p)$  is a twice continuously differentiable, linearly homogeneous function that is increasing and strictly quasi concave in its arguments. The production function in (1) implies that there is no substitutability between land and the other two factors of production, and that the potential output of the farm is determined entirely by the amount of land.  $g_1(K_1, L_p)$  can be interpreted as an aggregate of the capital and labor inputs in period 1. We assume that labor is an essential input in period 1, that is, that  $g_1(K_1, 0) = 0$  for all  $K_1$ . The parameter  $b$  is introduced to capture land-augmenting technical change, while  $a$  is introduced to simulate Hicks-neutral technical change.

In period 2, the tasks performed by labor are mostly Type 2 variety. We shall assume that in period 2, casual and permanent labor

are perfect substitutes and both will be employed to do Type 2 tasks. Now the output of the second period will depend nontrivially on the activities of the first period. More precisely,  $q_1$  is an intermediate input and we write the second period's output (the final product),  $q_2$ , as

$$(2) \quad q_2 = \min \{ g_2(K_2, L_p + L_c), q_1 \},$$

where  $K_2$  is the amount of capital used in period 2, and  $g_2$  is a twice continuously differentiable, linearly homogeneous function, increasing and strictly quasi concave in its arguments. The motivation for (2) lies in the interpretation of  $q_1$  as the quantity of unharvested crop and  $q_2$  as the quantity of the final product, that is, the harvested and threshed crop;  $q_1$  is thus a natural upper bound on  $q_2$ .

The price of the output is assumed to be exogenously fixed—set in the world market, say—and is normalized to unity. All farmers are assumed to be price takers in the labor and capital markets. For convenience, we assume that all farms are identical. Then in view of the linear homogeneity of (1) and (2), we can aggregate all farmers into a single price-taking farmer. The quantity  $h$  now represents the total arable land in the economy and is assumed fixed;  $L_p, L_c, K_1, K_2, q_1$ , and  $q_2$  can similarly be interpreted as aggregates. The wage rate of a permanent worker is  $w_p$  per period, while that of a casual worker is  $w_c$ . The rental rate on capital equipment per period, assumed exogenous, is  $r_i$ ,  $i=1,2$ . Since the types of capital used in the two periods are not necessarily the same, we can have  $r_1 \neq r_2$ .

#### A. Demand Side

We now turn to the optimal choices of  $L_p$ ,  $L_c$ , and  $K_i$ ,  $q_i$ ,  $i=1,2$ . Consider the production of a typical crop. First note that the optimal choice of factor inputs in period 2 depends on  $L_p$  and the decisions of the first period. The landlord's decision making must thus be foresighted and must be made with full awareness of how the choice of  $L_p$  and his period 1 decisions will impinge on period

2's choices. In what follows we shall adopt the convention that all expenses (wages and rentals) are incurred at the end of the period.

Given the nature of the production functions and the assumption of a constant and exogenously determined price for the final product, it follows that if production is at all viable, as we assume it is, it is profitable to cultivate all of the arable land. The profit-maximizing output levels in the two periods are

$$(3) \quad q_1 = q_2 = abh.$$

Without loss of generality we shall set  $h=1$ . The factor inputs will thus be determined so as to minimize the total present value cost of producing the outputs in (3). Since the landlord's choices of capital and casual labor are dependent on the amount of permanent labor hired, we first determine his demands of  $K_1$ ,  $K_2$ , and  $L_c$  conditional on his choice of  $L_p$ .

Define the cost functions

$$(4) \quad C_2(q_2, r_2, w_c) \\ \equiv \min_{K_2, L_a} \{ r_2 K_2 + w_c L_a \mid g_2(K_2, L_a) \geq q_2 \},$$

where  $L_a \equiv L_p + L_c$  is the aggregate amount of labor used in period 2, and

$$(5) \quad C_1(L_p, q_1/a, r_1) \\ \equiv \min_{K_1} \{ r_1 K_1 \mid g_1(K_1, L_p) \geq q_1/a \}.$$

At the profit-maximizing output levels given by (3), Shephard's Lemma yields the following factor demands:

$$(6a) \quad K_1^d(L_p, b, r_1) = \frac{\partial C_1}{\partial r_1}(L_p, b, r_1),$$

$$(6b) \quad K_2^d(ab, r_2, w_c) = \frac{\partial C_2}{\partial r_2}(ab, r_2, w_c),$$

$$(6c) \quad L_a^d(ab, r_2, w_c) = \frac{\partial C_2}{\partial w_c}(ab, r_2, w_c).$$

FIGURE 1. DETERMINATION OF THE DEMAND FOR PERMANENT LABOR

The casual labor demand is thus given by

$$(6d) \quad L_c^d(ab, L_p, r_2, w_c) \\ = \max \{ L_a^d(ab, r_2, w_c) - L_p, 0 \}.$$

The optimal choice of  $L_p$  is now determined as the solution to

$$(7) \quad \min_{L_p} r_1 K_1^d(L_p, b, r_1) + \beta r_2 K_2^d(ab, r_2, w_c) \\ + (1 + \beta) w_p L_p + \beta w_c [L_a^d(ab, r_2, w_c) - L_p],$$

assuming that the amount of casual labor hired is strictly positive. In (7)  $\beta$  ( $0 < \beta < 1$ ) denotes the per period discount factor. The first-order condition associated with (7) is

$$(8) \quad -r_1 \left( \frac{\partial K_1^d}{\partial L_p} \right) (L_p, b, r_1) \\ = (1 + \beta) w_p - \beta w_c \equiv z.$$

The demand for permanent labor,  $L_p^d(b, r_1, z)$ , is implicitly determined as the solution to (8). Twice continuous differentiability and the strict quasi concavity of  $g_1(K_1, L_1)$  implies that the left-hand side of (8) is declining in  $L_p$ . Thus  $L_p^d$  is decreasing in  $z$  (see Figure 1).

Together,  $L_p^d(b, r, z)$  and the expressions (6a)–(6d) constitute the demand side of our model. We now turn to the supply side.

### B. Supply Side

Consistent with Bardhan's (1979b) empirical evidence that the agricultural labor supply exhibits low elasticity in the peak period, though it may be fairly elastic in the slack period, we posit the utility function of an agricultural worker to be of the form

$$(9) \quad U(y, e, l) = (y - el)^\gamma; \quad 0 < \gamma < 1,$$

where  $y$  is the income received for the period and  $l$  is the fraction of the period for which he is employed ( $l=1$  if he is hired for the entire period). For an arbitrarily given  $e$  and wage rate  $w$ , the supply response  $l^*(w, e)$ , of a worker is obtained as the solution to

$$(10) \quad \max_l U(wl, e, l) \quad \text{such that } l \leq 1.$$

The maximization in (10) yields the labor supply response:

$$(11) \quad l^*(w, e) \begin{cases} = 0 & \text{for } w < e \\ \in (0, 1) & \text{for } w = e \\ = 1 & \text{for } w > e, \end{cases}$$

and an indirect utility function

$$(12) \quad V(w, e) = \{(w - e)l^*(w, e)\}^\gamma.$$

Since  $V$  is a decreasing function of  $e$ , there is an obvious moral hazard problem under a fixed wage contract, which makes the monitoring of effort imperative. Since Type 2 tasks are easy to monitor, we shall assume that workers performing these tasks can be costlessly supervised. There is thus little reason to hire these workers on long-term contracts, and the conventional means of hiring them, namely, on the spot markets, serves adequately.

With workers performing Type 1 tasks the situation is, however, quite different. We have defined Type 1 tasks as those that involve some discretion and judgment, and are dif-

ficult to monitor. Our discussion in the introduction leads to the following view on the nature of contracts given to workers performing Type 1 tasks.

In order to provide a self-enforcing (incentive) contract, the landlord offers Type 1 workers a permanent contract (over the infinite horizon),<sup>7</sup> in which the worker receives a wage  $w_p$  per period in exchange for the worker's services for the fraction  $l^*(w_p, \bar{e})$  of each period at an effort level  $\bar{e}$ . The worker's effort in period 1 is assumed to be accurately imputable at the end of the year. If the worker is found to have shirked, he is fired at the end of the crop.<sup>8</sup> He is, however, paid his wage,  $w_p$ , for each of the two periods. Once a Type 1 worker is fired, he cannot be rehired except as a casual worker.<sup>9</sup> If  $w_p$  is high enough that a worker's increase in utility from shirking in one period is more than offset by the discounted loss in his utility in having to join the casual labor force, he would never shirk.

It is important to spell out the terms required for the viability of such a contract to permanent workers. First, since a permanent worker's effort can be gauged only at the end of the second period, he can be fired only at the end of period 2. If the landlord concludes that the worker has shirked and decides to fire him, he must still be contractually committed to pay him the prenegotiated wage  $w_p$  in each of the two periods. Without such a contractual commitment, the landlord cannot be trusted to pay even honest workers

<sup>7</sup>While the assumption of infinite time horizon is analytically convenient, it is also empirically appropriate when a permanent worker's status can be inherited.

<sup>8</sup>It might be argued that the landlord would be indifferent between retaining the disloyal worker and replacing him with another who has exactly the same propensity to shirk. A permanent worker who realizes this cannot be deterred from shirking. Since the credibility of the system is at stake, however, the landlord would strictly prefer to replace the disloyal worker, establishing his reputation as a firm enforcer of contracts.

<sup>9</sup>This is assumed for simplicity. For our purposes it is enough if he can secure another such contract only with a probability that is strictly less than unity. This would lead to a discretely lower present value expected earning if he is fired.

and no worker would accept the contract. It may be argued that the fear of notoriety and the consequent difficulty in finding labor would keep the landlord honest. We feel, however, that in a labor surplus economy, reputation can hardly be as effective a check on the behavior of the owner of the scarce factor (land) as it is on the behavior of laborers competing for permanent jobs. Reputation is an effective weapon against moral hazard only for the suppliers of those factors that are in excess supply. The method of eliciting the desired level of effort from an employee by keeping him over his opportunity utility serves precisely to create such an excess supply so that reputation matters.

Another valid question is why a casual worker who failed to secure a permanent contract does not entice the landlord into offering him such a contract by posting a bond, the present value of which is marginally less than the difference in the present values of the lifetime income streams of the permanent and casual workers. Once again, such an arrangement is not viable due to the possibility of moral hazard on the part of the landlord; he always has the incentive to claim at the end of the period that the worker has shirked and thus expropriate the bond. Besides, as Eaton and White (1982) have pointed out, a worker faced with asset constraints may be unable to raise the amount necessary to post such a bond.

We can determine  $w_p$  in terms of  $w_c$  as follows. Assuming, for simplicity, that workers discount their utility at the same rate  $\beta$  as the landlord discounts profits, the present value utility of a permanent worker who is honest (i.e., who never shirks) is given by<sup>10</sup>

$$(13) \quad J_p^h(w_p, \beta) = V(w_p, \bar{e}) / (1 - \beta).$$

Now the opportunity utility of a permanent worker is the utility he would receive as a casual worker. Assume that the casual labor demand is spread uniformly across all the casual workers. Then the discounted lifetime

utility of a casual worker is given by

$$(14) \quad J_c(w_c, \beta) = (\beta / (1 - \beta^2)) V(w_c, \bar{e}).$$

We now turn to the possibility of shirking on the part of a permanent worker. Since any shirking is guaranteed to result in termination at the end of the second period of the same crop, a permanent worker who chooses to shirk will find it optimal to set  $e = 0$  in the first period. Since in period 2 he performs only menial tasks, which can be costlessly monitored, shirking is not possible. His discounted utility over this crop (relative to the beginning of the crop) is

$$V(w_p, 0) + \beta V(w_p, \bar{e}).$$

Further, assuming demand and supply conditions to be identical across all years, a permanent worker who contemplates shirking will do so in the very first year. Thus the discounted lifetime utility of a permanent worker who shirks is

$$(15) \quad J_p^s(w_p, w_c, \beta) = V(w_p, 0) + \beta V(w_p, \bar{e}) + \beta^2 J_c(w_c, \beta).$$

To ensure that a permanent worker never shirks, we simply require

$$(16) \quad J_p^h(w_p, \beta) \geq J_p^s(w_p, w_c, \beta).$$

For given  $w_c$  and  $\beta$ , inequality (16) puts a lower bound on the permanent worker's wage,  $w_p$ , which will elicit the required level of effort. At any  $w_p$  that satisfies (16) a worker obtains a strictly higher utility in a permanent contract than in a series of spot contracts:<sup>11</sup>

$$(17) \quad J_p^h(w_p, \beta) > J_c(w_c, \beta).$$

<sup>11</sup> This can be seen by rewriting inequality (16) as

$$(1 - \beta + \beta^2) V(w_p, \bar{e}) \geq (1 - \beta) V(w_p, 0) + \frac{\beta^3}{1 + \beta} V(w_c, \bar{e}) > (1 - \beta) V(w_p, \bar{e}) + \frac{\beta^3}{1 + \beta} V(w_c, \bar{e}),$$

by (12), so that  $(1 + \beta) V(w_p, \bar{e}) > \beta V(w_c, \bar{e})$ .

<sup>10</sup> This assumes that there is no saving, so that consumption and income are identical.

It follows that the number of permanent workers hired will be demand determined in general. Since a laborer strictly prefers being a permanent worker to being a casual worker, there will generally be an excess supply of workers seeking permanent contracts. This, however, will not result in a downward pressure on the permanent workers' wage, since any wage which is lower than the smallest  $w_p$ , say  $\bar{w}_p(w_c, \beta)$ , that satisfies (16) for given  $w_c$  and  $\beta$  is not credible: it leaves an incentive for the permanent worker to shirk. A casual worker who seeks to obtain a permanent contract by offering to work for a wage marginally less than  $\bar{w}_p$  will find that the landlord will not entertain the offer.

In the next section, we shall find that the behavior of  $\bar{w}_p(w_c, \beta)$  as a function of  $w_c$  is of crucial importance in determining the response of the agricultural economy to various exogenous changes. This behavior is recorded in the following proposition.

**PROPOSITION 1:** *For  $w_c \geq \bar{e}$ , an increase in  $w_c$  warrants a change in  $w_p$ , that is, (a) positive, and (b) if  $\bar{w}_p(w_c, \beta) < w_c$ , then*

$$(18) \quad d\bar{w}_p/dw_c < \beta/(1 + \beta).$$

(Proof: See the Appendix.)

Part (a) of Proposition 1 is eminently reasonable, since an increase in  $w_c$  amounts to an increase in the permanent worker's opportunity income (and utility). According to part (b), when the permanent worker's per period wage rate  $\bar{w}_p(w_c, \beta)$  is less than that of a casual worker's,  $w_c$ , the increase ( $\Delta w_p$ ) that is required to compensate a permanent worker for an exogenous increase ( $\Delta w_c$ ) in a casual worker's wage rate satisfies the inequality

$$(19) \quad (1 + \beta)\Delta w_p - \beta\Delta w_c < 0.$$

This implies that the increase in present value cost of engaging a permanent worker is less than that of a casual worker.

We now turn to the determination of the equilibrium. The equilibrium levels of capital in the two periods are demand determined.

Since permanent workers are held above their opportunity utilities, their number,  $L_p^*$ , is also demand determined:

$$(20a) \quad L_p^*(b, r_1, z) = L_p^d(b, r_1, z).$$

The demand for casual workers, we have seen, is given by

$$(20b) \quad L_c^d(L_p, ab, w_c, r_2) = L_c^d(ab, r_2, w_c) - L_p^*(b, r_1, z),$$

assuming the demand to be strictly positive. Next, we have the condition (16), which translates into

$$(20c) \quad V(w_p, \bar{e})/(1 - \beta) \geq V(w_p, 0) + \beta V(w_p, \bar{e}) + (\beta/(1 - \beta^2))V(w_c, \bar{e}).$$

For any  $w_c$ , (20c) determines the minimum  $w_p$  that will prevent a permanent worker from shirking.

Note that an equilibrium must have  $w_c \geq \bar{e}$  and  $w_p \geq \bar{e}$ , in view of (11). Note also that  $w_p = \bar{e}$  is never a solution to (20c) when  $w_c \geq \bar{e}$ . Thus we must have  $w_p > \bar{e}$ , and consequently,  $L^*(w_p, \bar{e}) = 1$  for a permanent worker. In other words, each permanent worker provides one efficiency unit of labor per period. Let  $N$  be the (exogenously given) total number of workers in the agrarian economy. The aggregate supply of casual labor in the second period,  $L_c$ , is then given by

$$(20d) \quad L_c^s \begin{cases} = 0, & \text{for } w_c < \bar{e} \\ \in (0, N - L_p^*) & \text{for } w_c = \bar{e} \\ = N - L_p^* & \text{for } w_c > \bar{e}. \end{cases}$$

This completes the specification of our model. Exogenous to the model are the production and utility functions, the discount factor, the rental rates on capital, and the total labor force. Endogenous to the model are the wage rate of the permanent and casual workers, the number of permanent workers, the number of efficiency units of

FIGURE 2. AN EQUILIBRIUM WITH UNEMPLOYMENT IN PERIOD 1 AND FULL EMPLOYMENT IN PERIOD 2

casual workers hired in the second period, and the amounts of capital hired in each of the two periods. These are obtained as the solution to the general equilibrium system defined by (20a)–(20d). The employment of capital is demand determined, that is, by (6a) and (6b).

Since a permanent worker's contract extends over the infinite horizon, the hiring of a permanent laborer represents a sunk cost for the landlord. The choice of the labor mix between permanent and casual workers can thus be viewed as a choice between sunk and variable costs.

For an arbitrarily chosen value of  $L_p$ , the casual labor supply is given by the kinked curve  $L_c^s$  in Figure 2. The demand for casual labor, contingent on the choice of  $L_p$ , is obtained from (20b) and is also shown in the first quadrant of Figure 2. The casual labor market clears at the wage rate  $w_c^*$ . (In what follows stars denote equilibrium values.) The second quadrant displays the solution for  $w_p$

in terms of  $w_c$  as obtained from (20c). Associated with a casual labor wage rate  $w_c^*$  is a permanent labor wage rate  $w_p^*$ . The fourth quadrant displays the demand for permanent labor as a function of  $w_p$  when the casual labor wage rate is  $w_c^*$ . For convenience this demand for permanent labor is measured from  $O'$  (along the horizontal axis). If we have indeed located an equilibrium, the demand for permanent labor at  $w_p^*$  will be exactly equal to the  $L_p$  with which we began our construction. Thus the situation illustrated in Figure 2 represents an equilibrium of the system of equations (20a) through (20d).

Given our assumption that the number of casual workers hired is strictly positive, two distinct situations can emerge as equilibria, although both of these are not equally relevant:

$$\text{Case 1: } 0 < L_p^* < N; 0 < L_c^* < N; \\ L_p^* + L_c^* < N.$$

FIGURE 3. AN EQUILIBRIUM INVOLVING UNEMPLOYMENT IN PERIODS 1 AND 2

This situation is illustrated in Figure 3. The demand for casual labor in the peak season is not enough to warrant full employment: there is some unemployment at the equilibrium casual wage rate  $w_c^* = \bar{e}$ .

Case 2:  $0 < L_p^* < N$ ;  $0 < L_c^* < N$ ;  
 $L_p^* + L_c^* = N$ .

This is the situation we considered in Figure 2. Here the supply of labor is a binding constraint in the second period and  $w^* > \bar{e}$ .

Of these two cases, the empirically relevant one is Case 2—in which only part of the labor force is hired on a permanent basis, while in the peak season there is no unemployment. In what follows, therefore, we shall focus exclusively on this case.

## II. Results

We now turn to the comparative static results of our model. These results depend crucially on whether the casual wage rate exceeds or falls short of the wage rate of the permanent workers. These are, of course, endogenously determined and our model allows for both possibilities. However, since our purpose here is to confront our predictions with what empirical evidence there is,

we pursue the empirically relevant case. From Richards (1979), Sanghavi, Ashok Rudra (1982), and Rakesh Basant (1984), we gather this case to be one where

$$(21) \quad w_c^* > w_p^*.$$

In what follows we shall assume (21) to be true.<sup>12</sup> (The signs of the comparative static results below are reversed when (21) is violated.) Defining

$$z^* = (1 + \beta)w_p^* - \beta w_c^*.$$

we see from (18) that

$$(22) \quad \frac{dz^*}{dw_c^*} = (1 + \beta) \left[ \frac{dw_p^*}{dw_c^*} - \frac{\beta}{1 + \beta} \right] < 0.$$

That is, the difference in the present value cost of hiring a permanent worker over that of hiring a casual worker declines with  $w_c^*$ . This fact is used in establishing the comparative static properties of our model, which are recorded in the following proposition.

**PROPOSITION 2:** *In an equilibrium corresponding to Case 2,*

- (a) *an increase in  $N$  decreases the proportion of permanent contracts,*
- (b) *an increase in  $a$  (or  $b$  or both) increases the number of permanent contracts,*
- (c) *an increase in  $a$ , with  $ab$  held constant, decreases the number of permanent contracts,*
- (d) *an increase in  $r_1$  or  $r_2$  increases the number of permanent contracts.*

(Proof: See the Appendix.)

Parts (a) and (b) of Proposition 2 provide explanations, alternative to Bardhan's (1983), for certain empirical observations on permanent labor. According to (a), the proportion of permanent workers is higher the tighter the labor market. A reduction in the supply of agricultural labor,  $N$ , increases the peak season casual wage rate,  $w_c^*$ . This results in

<sup>12</sup> Full employment in the peak period is a necessary condition for this to hold. It is also necessary that the permanent workers not discount the future too heavily.

an increase in the wage rate of the permanent workers,  $w_p^*$ . However, the increases satisfy inequality (19)—implying that the marginal permanent worker is becoming cheaper to hire relative to a casual worker in period 2—inducing a substitution of permanent for casual workers. Part (a) above explains the dramatic increase in the percentage of permanent contracts in East Prussian agriculture in the first half of the nineteenth century. During this period there was an increase in the cultivated area by almost 90 percent between 1815 and 1849, and a simultaneous agrarian reform resulted in peasants losing land to large landlords. The loss of land forced the peasants into the labor market. Richards (1979), however, estimates that the total net loss of land by the peasants to the landlords may have been as low as 3 percent, implying an overall decrease in the labor-to-land ratio, resulting in a higher proportion of permanent workers.

Part (b) of Proposition 2 implies that a yield-increasing improvement in the technology, either through a Hicks-neutral technical change (i.e., higher  $a$ ) or through a land-augmenting technical change (i.e., higher  $b$ ) would increase the proportion of permanent contracts. The intuition for this is the same as that for part (a), and hinges on the relative changes in the magnitudes of  $w_c^*$  and  $w_p^*$  triggered by the exogenous change. Bardhan (1983) provides empirical evidence based on the second Agricultural Labor Enquiry Data that the percentage of permanent labor in India is positively correlated with the index of land productivity.

The demand for permanent and casual labor is, of course, a derived demand. For simplicity we have assumed that the price of the output is exogenously given. It is clear, however, that any factor that affects the demand for output will have repercussions on the labor composition in equilibrium. In particular, an increase in the output price will induce an increase in the output for production functions more general than the ones we have adopted. The effects of an increase in the price of the output can, however, be simulated in our model by an increase in  $a$ . Part (b) of Proposition 2 then explains the impact of the opening up of export markets

on the labor composition in nineteenth-century Chile. In the 1860's, Chile began to export grain to European markets and this lasted until 1890. Bauer (1971) estimated that the percentage of casual workers in the rural labor force of central Chile fell from 72 percent in 1865 to 39 percent in 1895—an observation that is consistent with the result in part (b) of the above proposition.

While part (b) is of empirical interest since it is easily verifiable, an exercise that is of theoretical interest is contained in part (c). Here the final output is held fixed and the burden of activity is shifted across the two periods. We see that an increase in  $a$ , implying a decrease in  $b$ , makes cultivation less intensive in the first period while increasing the activity in the peak season. Since in the second period casual and permanent labor are substitutable, we observe a shift from permanent to casual labor. Thus Jan Breman (1974) observes that a change in crops from rice (which has a relatively even distribution of tasks over the two periods) to mangoes (which has a very heavy labor demand in period 2) resulted in the replacement of permanent contracts by casual labor contracts in Gujarat, India. Kalpana Bardhan (1977) has also made similar empirical observations.<sup>13</sup>

Part (d) of Proposition 2 indicates that a decrease in the rental cost of the type of capital used in the first period would displace permanent workers and consequently increase the use of casual labor in the second period. It could be argued that in India, in view of the notoriously imperfect capital markets, farms with tractors are those for which the owners face lower capital costs. If tractors were employed on such farms only during period 1 (for operations such as ploughing and sowing), the result would be a displacement of permanent workers and an increase in the use of casual workers. While

<sup>13</sup>Part (c) of Proposition 2 is also consistent with empirical evidence that increases in the cropping intensity, which would result in a more even labor demand profile, are correlated with higher incidence of permanent contracts. See K. Bardhan on India, and Richards (1979) on East Prussia.

the existing empirical literature (Rudra; Bina Agarwal, 1981) bears out our prediction regarding permanent workers, there is conflicting evidence on the effect on the employment of casual workers. We conjecture that this conflict arises because tractors are used on some farms for period 1 operations only, while on others they are also used in period 2.

An interesting feature of the result in part (d) of Proposition 2 is the implied complementarity between the capital used in the two periods. Since there are no sunk costs involved in the use of capital (they are presumed to be rented separately in each period), one might expect the choice of the amount of capital used in period 1 to be independent of  $r_2$ . This, however, is not so. A decline in  $r_2$  increases the demand for  $K_2$  and reduces the demand for casual labor. Given full employment in the second period, this lowers the casual wage rate, which in turn lowers the wage rate of permanent workers. In view of (18), however, permanent workers are becoming relatively more expensive than casual workers and this induces a substitution away from permanent labor. The reduction in the amount of permanent labor hired warrants an increase in  $K_1$  since, in the first period, these two inputs are substitutable. A policy implication of this result is that any governmental effort to alleviate labor-supply bottlenecks in the peak period by lowering  $r_2$  (through subsidies, for example) would have an adverse effect on the employment of labor in the slack period.

### III. Conclusions

In this paper we have presented the view that the institution of permanent workers exists to elicit loyalty and trustworthiness from hired workers, so that they can be entrusted with important tasks that are inherently difficult to monitor. This is accomplished by holding them at a higher-than-opportunity utility, and thus creating in the process two tiers within a homogeneous labor force. Evidence of disloyal behavior (i.e., shirking) results in the termination of the permanent contract and the possibility of

the consequent discrete fall in the utility keeps the worker loyal.<sup>14</sup>

A well-known result in the agency literature states that a threshold contract with a discontinuous reward system can be devised to elicit the optimal amount of effort from a worker. The incentive mechanism implicit in permanent contracts within a two-tiered labor force is, however, not a special case of this. A contract which stipulates the agent's reward in terms of his effort when the verdict on the latter is pronounced *ex post* by the principal will not be accepted by the agent. The possibility of morally hazardous behavior on the part of both the principal and the agent has to be explicitly recognized. In the institution we have discussed, the relationship between the principal and the agent involves repeated transactions and this facilitates the design of a contract which gets around the above difficulty. The landlord is contractually committed to pay the permanent worker the full stipulated income for the year even if he is fired at the end of the year. In other words, the compensation goes with the position; as long as a worker is in the higher tier he receives a compensation appropriate to this position. The contract is thus incentive compatible for both parties despite the inherent problem that there is no objective criterion by which to gauge the worker's effort level.

Long-standing relationships that involve repeated transactions between two parties and put a premium on loyalty and trust are referred to as patron-client relationships.

<sup>14</sup>Note that the assumption of a homogeneous labor force is not essential to our theory. With heterogeneous alternative employment opportunities across workers, casual workers with high opportunity incomes may not prefer permanent contracts. Even so, our theory remains valid as long as there is an excess supply of some casual workers desiring permanent jobs. Bardhan and Rudra (1981) found, in a survey conducted in West Bengal (India), that the bulk of the casual workers preferred casual contracts and the bulk of the permanent workers preferred permanent contracts. However, a statistical test performed on their data leads us to reject the hypothesis that there is no excess supply of workers desiring permanent contracts in favor of the hypothesis of a strictly positive excess supply.

These relationships are often sustained and strengthened by means of implicit contracts. The patron (the principal) maintains the client (the agent) at a higher-than-opportunity utility through patronage to win the client's loyalty and trust. The instruments used to effect this patronage will vary according to the needs of the client and the ability of the patron to supply these needs. Ideally, the instruments will bestow a large benefit on the client at a relatively low cost to the patron. Provision of land plots in labor-scarce economies, consumption credit in an environment of imperfect capital markets or protection in the dubious legal environment of Sicily are examples of instruments of patronage. As discussed in this paper, the seasonal nature of agriculture renders it relatively easy for landlords to maintain a utility-differential between permanent and casual workers.

Even in industrialized economies we observe contracts that resemble those of permanent workers. In particular, in sectors subject to seasonal demand (such as construction, services catering to tourism, recreational vehicle services, etc.) firms retain year-round a core of permanent workers selected from the same pool as the seasonal workers. We further conjecture that the most familiar type of employment contract, namely, the salaried contract of a white-collar worker (in a position that is inherently difficult to monitor), embodies a supervision mechanism similar to the one discussed in this paper.

The institution of permanent workers is a graphic manifestation of the consequences of the supervision principle proposed by Eaton and White (1983). This principle, however, is quite general in scope. For example, it explains a fact that forms the premise of numerous models in the migration literature: the substantial wage differential that exists between newly recruited factory workers and those in the informal urban sector from which they are recruited.

Indeed, this incentive mechanism does not even require that the transaction between the principal and agent be voluntary. The mechanism could work equally well in a slave economy. What is essential is that the agent

be convinced in a credible fashion that there is a state of existence that is discretely worse than his current one. Even the miserable existence of a slave can be made worse by selling him and separating him from his family. More subtle means employed to create a favored status among slaves in the antebellum South are discussed by Robert Fogel and Stanley Engerman (1974). Thus even when crude supervision devices such as physical punishment are permitted by society, subtle incentive mechanisms that reduce the cost of supervision have always played an important role. The study of historical institutions and their incentive structures could, therefore, be quite useful in the construction of a theory of economic organizations.

#### APPENDIX

##### PROOF of Proposition 1:

(a) Substituting (13), (14), and (15) in (16), which holds with equality at  $\bar{w}_p$ , we have

$$(A1) \quad V(\bar{w}_p, \bar{e})/(1-\beta) = V(\bar{w}_p, 0) + \beta V(\bar{w}_p, \bar{e}) + (\beta^3/(1-\beta^2))V(w_c, \bar{e}).$$

Differentiating the above expression totally with respect to  $w_c$  and rearranging, we obtain

$$(A2) \quad \frac{d\bar{w}_p}{dw_c} = \left[ \left[ \beta^3/(1+\beta) \right] \frac{\partial V}{\partial w_c}(w_c, \bar{e}) \right] / \left[ (1-\beta+\beta^2) \frac{\partial V}{\partial w_p}(\bar{w}_p, \bar{e}) - (1-\beta) \frac{\partial V}{\partial w_p}(\bar{w}_p, 0) \right].$$

The numerator of the right-hand side is clearly positive. Note that for (A1) to hold we must have  $\bar{w}_p > \bar{e}$ . Using (11), it follows from (12) that

$$(A3) \quad \frac{\partial V}{\partial w_p}(\bar{w}_p, \bar{e}) > \frac{\partial V}{\partial w_p}(\bar{w}_p, 0),$$

so that from (A2)

$$(A4) \quad d\bar{w}_p/dw_c > 0.$$

(b) From (A3), we see that the denominator of the right-hand side of (A2) exceeds

$$(1 - \beta + \beta^2) \frac{\partial V}{\partial w_p}(\bar{w}_p, \bar{e}) - (1 - \beta) \frac{\partial V}{\partial w_p}(\bar{w}_p, \bar{e}) = \beta^2 \frac{\partial V}{\partial w_p}(\bar{w}_p, \bar{e}).$$

Thus from (A2) we have

$$\frac{d\bar{w}_p}{dw_c} < \frac{\beta}{1 + \beta} \left[ \frac{\partial V}{\partial w_c}(w_c, \bar{e}) / \frac{\partial V}{\partial w_p}(w_p, \bar{e}) \right]$$

If  $\bar{w}_p(w_c, \beta) < w_c$ , it follows by differentiating (12) that the term in the square bracket is less than unity, so that  $d\bar{w}_p/dw_c < \beta/(1 + \beta)$ .

PROOF of Proposition 2:

First, note that  $K_1^d(L_p, b, r_1)$ , which is obtained as the solution to the trivial optimization in (5) with  $q_1 = ab$ , has the following comparative static properties:

$$(A5) \quad \frac{\partial K_1^d}{\partial L_p}(L_p, b, r_1) < 0,$$

$$\frac{\partial K_1^d}{\partial b}(L_p, b, r_1) > 0, \quad \frac{\partial K_1^d}{\partial r_1}(L_p, b, r_1) = 0.$$

The comparative static properties of  $L_p^d(b, r_1, z)$ , obtained by differentiating (8), using (A5) and the strict quasi concavity of  $g_1(K_1, L_p)$ , are easily seen to be given by

$$(A6) \quad \frac{\partial L_p^d}{\partial b}(b, r_1, z) > 0,$$

$$\frac{\partial L_p^d}{\partial r_1}(b, r_1, z) > 0, \quad \frac{\partial L_p^d}{\partial z}(b, r_1, z) < 0.$$

If we let  $\alpha$  denote an exogenous shift param-

eter whose comparative static effects we wish to determine, we may write

$$(A7) \quad \frac{dL_p^*}{d\alpha} = \frac{\partial L_p^d}{\partial \alpha}(b, r_1, z^*) + \frac{\partial L_p^d}{\partial z^*}(b, r_1, z^*) \frac{dz^*}{dw_c^*} \frac{dw_c^*}{d\alpha},$$

recalling that the number of permanent workers is demand determined. From (20b) and (20d), we have

$$(A8) \quad L_a^d(ab, r_2, w_c^*) = N.$$

Totally differentiating this with respect to  $\alpha$  and rearranging, we have

$$(A9) \quad \frac{dw_c^*}{d\alpha} = \left( \frac{dN}{d\alpha} - \frac{\partial L_a^d}{\partial \alpha} \right) / \left( \frac{\partial L_a^d}{\partial w_c} \right).$$

The comparative static properties of  $L_a^d(ab, r_2, w_c)$ , which is obtained as the solution to the optimization problem (4), are easily verified to be

$$(A10) \quad \frac{\partial L_a^d}{\partial r_2}(ab, r_2, w_c) > 0,$$

$$\frac{\partial L_a^d}{\partial w_c}(ab, r_2, w_c) < 0, \quad \frac{\partial L_a^d}{\partial (ab)}(ab, r_2, w_c) > 0.$$

(a) Since  $\partial L_a^d/\partial N = 0$  and  $\partial L_a^d/\partial w_c < 0$ , (A9) yields  $dw_c^*/dN < 0$ . Further, since  $\partial L_p^d/\partial N = 0$ , we have from (A7) and (22) that  $dL_p^*/dN < 0$ .

$$\therefore \frac{d}{dN}(L_p^*/N) = -\frac{1}{N^2}L_p^* + \frac{1}{N} \frac{dL_p^*}{dN} < 0.$$

(b) Since by (A10)  $\partial L_a^d/\partial a > 0$ , we have  $dw_c^*/da > 0$  from (A9), so that from (A7) we have  $dL_p^*/da > 0$ . As above,  $dw_c^*/db > 0$  since  $\partial L_a^d/\partial b > 0$ . Also, since  $\partial L_p^d/\partial b > 0$ , it follows from (A7) that  $dL_p^*/db > 0$ .

(c) When  $a$  changes but  $ab$  is held constant, we see from (A8) that  $dw_c^*/da = 0$ .

Thus from (A7),

$$\text{sign} \left\{ \frac{dL_p^*}{da} \bigg|_{ab = \text{constant}} \right\} = \text{sign} \left\{ \frac{\partial L_p^d}{\partial a} (1/a, r_1, z) \right\} < 0.$$

(d) Since  $\partial L_a^d / \partial r_1 = 0$ , we have from (A9) that  $dw_c^* / dr_1 = 0$ .

$$\therefore dL_p^* / dr_1 = \partial L_p^d / \partial r_1 > 0.$$

Further, since  $\partial L_a^d / \partial r_2 > 0$ , it follows from (A9) that  $dw_c^* / dr_2 > 0$ . Since  $\partial L_p^d / \partial r_2 = 0$ , we have from (A7) that  $dL_p^* / dr_2 > 0$ .

# The Relative Inefficiency of Quotas: The Cheese Case

By JAMES E. ANDERSON\*

The nonequivalence of tariffs and quotas under a wide variety of circumstances is well established in economic theory. This study considers heterogeneity as a source of nonequivalence and demonstrates its practical importance. Where restriction is inevitable, the bias of economists in favor of price instruments is not thoroughly grounded; this study should help provide a foundation.

The point of departure from the equivalence model is differentiation of products. In practice, almost any quota system will be applied to what is in fact a commodity group. Legislators or chief executives restrict total imports of a group, possibly due either to lack of information or lack of a model which would allow a basis for derivation of a more detailed set of restrictions. Quota system administrators by default have wide authority to allocate trade within the group. Distribution of quota licenses in this case involves substantive resource allocation.

It is shown below that optimal allocation of quota licenses subject to a group total import constraint will produce uniform rent on use for each member of the group. This is equivalent to a uniform specific import tax save for revenue distribution. Administrators typically do not have competitive auctions in licenses that would accomplish the same end, but use simple rules such as base-year quantity or value proportions to hand out licenses that are type- and country-of-origin specific. Provided resale is frustrated, the allocation will be inefficient. Section I sets out the simple analytics of optimal and quantity proportion quota allocations and discusses factors influencing the size of inefficiency.

The purpose of this paper is to provide a case study of an import quota system with essentially the characteristics noted. Section II briefly discusses the U.S. dairy quota system. Section III reviews the econometric model of cheese demand used to calculate welfare effects. The results in Section IV demonstrate that the inefficiency loss is indeed substantial. The estimated AIDS model of the U.S. cheese quota system (see my 1983 paper) is used to calculate the welfare costs of the quota compared to an efficient tariff that produces the same aggregate quantity of cheese imports in the constrained categories. The analysis shows added cost amounting to over 15 percent of base expenditure on the constrained categories. Another revealing way of scaling the welfare cost compares the quota inefficiency loss with the total welfare loss from not having free trade. Switching from the quota to an efficient tax that yields the same quantity of imports gets us nearly one-third of the way back to free trade. Or, the quota distribution inefficiency adds nearly 50 percent to the unavoidable loss due to the constraint on imports.

Sections II and III discuss the considerable difficulties encountered in building an econometric model of the cheese quota system. The results of Section IV thus are subject to considerable bias, especially from aggregation, when regarded as a realistic account of the costs of the U.S. cheese quota system. This is unfortunate, but does not detract from the main point of this paper, which is to show a presumption that quota systems in practice are inefficient. The results of Section IV can be interpreted as plausible simulations of a quota system not unlike the U.S. cheese quota system. The size of the welfare loss together with the difficulties experienced in carrying on the study of quota incidence suggest that economists are on firm ground in opposing the trend toward use of quantity restrictions. Failing a return to price instruments, we should advocate data collec-

\*Professor of Economics, Boston College, Chestnut Hill, MA02167. This study was supported by NSF grant SES-7907085 to Boston College. Peter Dixon gave helpful comments, but should be held blameless for any remaining errors or obscurities.

tion in a manner which makes incidence analysis easier.

The results here are related to general propositions suggesting that aggregation seriously understates the deadweight loss of tax systems since aggregation reduces both estimated elasticities of substitution and estimated average taxes. See Peter Dixon (1978). The disaggregation of the model here avoids the type of bias Dixon studied, but, in addition, disaggregation by cheese type and countries uncovers a new source of loss worth over 15 percent of base expenditure on the restricted cheese categories. And even these results are based on a (forced) considerable aggregation of cheese types. Thus, painful as it is, disaggregation is strongly indicated for tax incidence problems.

### I. Efficient Quotas on Commodity Groups

Let us assume that political pressures result in an import quota to be applied to an aggregate commodity group. This takes the form of what Jagdish Bhagwati and T. N. Srinivasan (1983) call a "non-economic" constraint. Administration of the quota system is left to civil servants, who will typically use simple rules to allocate licenses under the constraint. While political interests build around the allocation systems, I regard these as second-order effects. They can be disregarded by an enlightened administrator who must nevertheless obey the legally mandated aggregate quota.

The optimal allocation is, intuitively, going to equalize rent on quota licenses across members of the group. This would be the equilibrium outcome of a competitive auction of licenses, and the inefficiency of any other allocation is seen to be a foregone arbitrage gain. The optimum can automatically be achieved by a uniform tax.<sup>1</sup>

<sup>1</sup>Formally, the analysis has much in common with that of Leslie Young and myself (1980). There the product differentiation was by states of nature. We analyzed optimal quota allocations across uncertain states subject to an average import constraint, and showed that the optimum is reached with a uniform tax. My article with Young (1982) considered constraints on other portions of the probability distribution of imports

Under alternative noneconomic constraints, a quota thus allocated "efficiently" can be inferior to, for example, an ad valorem tariff. The substitution toward higher value categories which reaps an arbitrage gain can also conflict with a noneconomic constraint on employment or revenue. See Robert Baldwin (1982) and Avinash Dixit (forthcoming). The issue of what constraint is appropriate is serious. It is always necessary to specify as closely as possible the deeper variable targeted by the political economic process and its relation to the trade control. Once this is done, ignorance of detailed elasticities and/or absence of a complete model will often necessitate an aggregate trade control.<sup>2</sup>

Consider the case of dairy quotas, for example. They arose out of a desire to limit domestic price support payments (see Section II below). This might imply a deeper noneconomic constraint on disturbing the subsidy budget by no more than a given amount. Possibly revenue raised on imports might also be relevant. Nevertheless it is reasonable to use an aggregate import constraint for two reasons. First, the stated objective of administrators was to place quotas on substitutable categories such that total annual imports of dairy products did not exceed a given milk equivalent tonnage, this being instrumental in limiting support payments to domestic producers (Section II). This effectively translates into a simple ag-

under uncertainty and we were able to rationalize tariff quotas, in which the tariff rate steps upward with import volume. In the present context of differentiated products, this translates into other constraints on distribution within the group besides the aggregate one. Again, analogous to our 1982 article, this will imply an optimum in which rents are equalized within subgroups. I should also note that everything said about quantitative restrictions and uniform specific taxes has immediate analogy with foreign exchange revenue restrictions and uniform ad valorem taxes. An inefficiently distributed quantity quota can, however, achieve higher welfare than an ad valorem tax in the achievement of a quantity constraint.

<sup>2</sup>This can have a variety of forms. For example, an efficiently applied constraint on foreign exchange value is indicated if employment is more closely linked to value than to quantity. Using the analysis above, this is readily seen to be equivalent to a uniform ad valorem tariff.

gregate quantity constraint. Presumably, administrators chose this objective because they were ignorant of demand elasticities when formulating quotas. By default all cheeses in a substitutable category were made identical. Second, optimizing the price support (possibly plus dairy import restriction revenue) subsystem is of dubious relevance when we observe that subsidy payments come from the general government revenue with little evidence of concern for magnitude as coverages change and when licenses are given away. Consideration of optimal fiscal systems, if it can be done sensibly at all, must be made a much bigger project. The simple noneconomic constraint is the natural primal analogue to partial equilibrium analysis.

Proceeding formally, I set out a simple analysis of a small trading country subject to a noneconomic constraint on aggregate imports within some group. The vector of import quantities in the constrained group is  $q = (q_1, \dots, q_m)$ . The vector of trade quantities in the other commodities is  $x$  (which contains positive elements for imports and negative elements for exports). Nontraded goods are irrelevant to the point I make, so are suppressed. External prices of  $q$  are given by the vector  $p$ , and external prices for the vector  $x$  are given by  $s$ . Allocation of production (if any in given categories) is irrelevant, so I assumed fixed endowments of goods that are produced;  $Z_1$  for constrained goods and  $Z_2$  for unconstrained goods.

The enlightened civil servant must choose a trade vector  $(q, x)$  to maximize utility of the representative consumer subject to the balance of trade constraint and the noneconomic constraint. Thus he solves the program:

$$(1) \quad \text{Max}_{q, x} U(Z_1 + q, Z_2 + x)$$

$$(\lambda) \quad p \cdot q + s \cdot x \leq 0$$

$$(\mu) \quad \iota \cdot q \leq \bar{q}$$

where  $Z_1, Z_2$  are constant production vectors,  $\mu$  and  $\lambda$  are Lagrange multipliers, and  $\iota$  is the vector of ones.

The first-order conditions are sufficient with concave utility, and yield in terms of a

numeraire from the unconstrained group:

$$(2) \quad (1/U_{2n})U_1 = p + (\mu/\lambda)\iota;$$

$$(1/U_{2n})U_2 = s,$$

where  $U_{2n} = \partial U / \partial x_n$  = marginal utility of the numeraire good,  $U_1 = \partial U / \partial q$ , and  $U_2 = \{\partial U / \partial x_i\}$ ,  $i \neq n$ .

The conditions (2) immediately imply that the unique global optimum can be decentralized with a uniform specific tax  $= \mu/\lambda$  on every element of  $q$ , the tariff proceeds being lump sum redistributed to the representative consumer. Equivalently, quota licenses can be competitively auctioned with redistribution of the proceeds.

In practice, quota licenses are usually distributed according to a simple rule, like quantity proportions in a base year. I now briefly consider theoretical factors affecting the magnitude of inefficiency created by such rules. With Leontief-type utility functions and endowments which grow radially (neutral growth), quantity rules will attain the optimal allocation in problem (1). Nonneutral growth of the  $Z$ s has an obvious effect. Less obviously, as the elasticity of substitution rises, two counteracting forces mediate the inefficiency of the rule. General analytical results are not attainable, but these forces are clear. First, the higher the elasticity of substitution, the less the harm associated with a given configuration of nonuniform taxes (equivalent to a quota distribution), since it is easier to substitute away from expensive categories. But second, the lower the elasticity of substitution, the less far the rule-given quantity restriction is from the optimal quantity change.

In simulation of the dairy quota system using a CES utility function and methods analogous to those of Section IV, the first effect predominated in a reasonable range of elasticity values (from 0.10 to 3), based on welfare loss relative to base expenditure. The second effect showed up when the inefficiency loss was scaled relative to the unavoidable inefficiency due to the constraint. This measure of relative inefficiency rose with the elasticity of substitution, but much more gently than the relative-to-base-expenditure measure fell. The latter typically dropped by

a factor of 10 in the range of elasticity values 0.10 to 1.0.

Similar exercises can be done for other rules or other utility functions. These results point to the sensitivity of empirical findings to the elasticities used, and thus emphasize the need for sound empirical work. The results of Section IV show large welfare losses; this and the theoretical analysis above indicate how easily a quantity rule can err badly.

## II. The U.S. Dairy Industry and the Quota System

I first consider the institutional and legal structure of dairy import controls and then the resulting market structure assumed. I aim to justify my use of 1) the simple form of "noneconomic" import constraint, and 2) a partial equilibrium model.

The U.S. dairy quota system originated as a by-product of the dairy price support price system. The main element is support of a manufacturing grade milk price, but there are also butter and American-type cheese support prices. At various times, beginning in 1937, quotas have been imposed on a variety of cheeses, as well as butter, nonfat dry milk, substances high in nonfat dry milk or butterfat, and other milk products. The president has very broad authority to proclaim, raise, or suspend these trade controls,<sup>3</sup> but in practice revision has been limited.

<sup>3</sup>Presidential authority for the quota is drawn from Section 22 of the Agricultural Adjustment Act of 1933 (originally added in 1935 and subsequently revised extensively). It directs the Secretary of Agriculture to advise the president whenever he has reason to believe any article is imported in such conditions and such quantities as to: 1) render or tend to render inefficient or materially interfere with any price support or stabilization program relating to agricultural commodities, or 2) reduce substantially the amount of any product processed in the United States from any agricultural commodity with respect to which any such program is being undertaken. If the president agrees there is reason for such belief, he directs the U.S. International Trade Commission to conduct an investigation and submit a report. The president is authorized, based on such findings, to impose such fees or quotas in addition to the basic duty as he shall determine necessary. The president may designate the affected article by physical qualities, value, use, or upon such other basis as he shall determine. The president may revise or suspend all previously proclaimed fees or quotas. Any decision by the president as to the facts under this authority is final.

In the timeless model of Section I, the quota allocation problem is faced once and for all. In practice, the set of dairy quotas reflect an evolution of broadening the scope of coverage as more products appear to be sufficiently substitutable with domestic products to warrant control. Thus the date of inception and benchmark period (upon which proportionate allocations are based) differ for different cheeses and other products. The spirit of the quota system is, however, to set detailed levels of imports on a basis consistent with historic proportions. The presidential authority does not stipulate that this principle is to be carried through to allocation by country of origin, but the administrators have so proceeded. An important implication of the evolving nature of the quota system is that the administrators help create the marginal changes in the system issued by the president. Significantly, they appear to regard their objective as a target level of milk equivalent tonnage in groups identified as substituting for domestic milk products. (See, for example, Harlan Emery, 1969, pp. 9-11.) Thus both the history of quota setting and the stated objective of the quota administrators supports a noneconomic constraint of the simple form in (1). I assume that any second-order political interests do not create binding constraints.

The current allocation system, on the other hand, does apparently create *economically* binding constraints. The USDA quota system administrators develop license allocation by commodity by country from base-year allocations in the legally mandated categories. They claim to have effective auditors who implicitly frustrate resale of licenses. Measured differences in average quota rent margins, reported below, bear the claim out. This creates the basis for my study of efficient alternative dairy product import controls.

Butter and other milk product quotas are ignored here on the grounds that they are rather simple undifferentiated products with low elasticity of substitution with cheese or with each other. On prior reasoning, the quota allocations in these categories might be reasonably appropriate. The group of cheese controls appears to represent a much closer approximation to the theoretical model

above. Cheese is a highly differentiated product with fairly high within-group elasticities of substitution. The Census trade data have nine commodity categories of continuously imported cheese plus a catchall, with six of the nine plus a part of the catchall category subject in part or whole to quota constraint. This creates the circumstances for a case study of quota inefficiency when we convert the quota constraints into an overall constraint on the six categories. Inefficiency will arise due to 1) inefficient allocation by country within the same cheese type (a matter of administrative discretion), and 2) inefficient allocation over types (partly mandated in current presidential proclamations, but presumably easily changed within the spirit of the presidents' previous exercises of authority).

I now rationalize a partial equilibrium approach to the market for imported cheese. The United States is a small consumer of foreign cheese, hence foreign price of foreign cheese is reasonably taken to be exogenous. Domestic price in quota constrained categories is of course endogenous. The U.S. consumption of cheese is a tiny fraction of total food consumption, so ignoring spillover effects onto noncheese prices may be reasonable. Domestic price of domestic cheese is endogenous save when the government is maintaining a floor price through large purchases. Endogenous prices are fitted to an implicit reduced form in the econometric work reported below.

In principle, it is possible to model the supply side of the domestic cheese industry. Domestic cheese production and sale is dominated by the government's milk, cheese, and butter price supports, but not entirely so. Successful dealing with these markets probably requires a model of how the government sets its supports. The highly politicized process attending this in the 1970's is common knowledge. An attempt to deal with modeling domestic cheese supply was dropped at an early stage because in the welfare (as opposed to econometric) analysis it is permissible to treat the U.S. price of U.S. cheese and related dairy products as exogenous to import policy changes, being separately set by the government and main-

tained by price support purchases. This is effectively true in a large part of the sample (1964-79), particularly in the later years. The displacement effect of foreign price changes on domestic cheese categories can be calculated using the demand functions for imported cheese and relying on the symmetry implied by demand theory. The implied change in price support purchases of domestic cheese is carried through as part of the analysis.

I now consider briefly problems of aggregation. With the data available it proved to be impossible to match exactly the quota constraints with the commodity categories. My solution was to aggregate. Quota authority lies with the USDA, with different statistical codes from the Customs (TSUS) code, which are different still from the Census (SITC) codes. Country-level quota information was available, but attempts to build a complete model of import supply were frustrated by aggregation problems and complexities in how quota licenses are used. (See the Appendix to my earlier paper for more detail.) The econometric model used in the next sections glosses over quota system complications by assuming that for each of the six categories constrained by quota, the entire set of members is treated uniformly. Foreign price of any cheese is exogenous, but domestic price of domestic cheese and all quota-constrained cheese is endogenous and fitted to an implicit reduced form. This creates aggregation bias of unknown sign and magnitude. Similarly, the welfare analysis is biased as a "true" account of the cost of U.S. quota system inefficiency.

### III. The Model of U.S. Imported Cheese Markets

The preceding section essentially justifies a partial equilibrium approach to modeling the effect of switching from quotas to tariffs. The U.S. domestic cheese prices are assumed to be made exogenous by government price support, other food prices are not affected, and the United States is a small customer in world dairy markets, hence foreign prices are exogenous. For the welfare evaluation, the endogenous variables are assigned their sample mean values in the quota regime.

For econometric modeling, U.S. domestic cheese prices are made endogenous (since they are at least some of the time) and the U.S. price of quota constrained foreign cheese is also endogenous. I thus evade modeling domestic supply of both foreign and domestic cheese except as it is embedded in an implicit reduced form. We do require a set of demand functions for imported cheese.

A nine-equation model of imported cheese demand is estimated for the years 1964–79. A food and beverage expenditure function is assumed to exist for a representative U.S. consumer identifiable in the aggregate data. (See my earlier paper for discussion of the implied assumptions.) The AIDS expenditure function is used, with the further wrinkle that only a tiny portion of total food and beverage consumption is estimated, that for nine imported cheeses. See Angus Deaton and John Muellbauer (1980a,b) for a general treatment of AIDS. The AIDS function is used because it is a flexible functional form with particularly simple capability for allowing nonhomothetic preferences while permitting exact linear aggregation.

The AIDS expenditure function is defined as

$$(3) \log e(p_1, \dots, p_n, u) = \sum_{i=1}^n \alpha_i \log p_i + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \gamma_{ij} \log p_i \log p_j + u\beta_0 \prod_{j=1}^n p_j^{\beta_j},$$

where  $u$  = utility indicator,  $e(\ )$  = expenditure function, and  $p_i$  = price of good  $i$ .

By Shephard's Lemma, the compensated demand functions are  $\partial e / \partial p_i = c_i(p_1, \dots, p_n, u)$ . It is more convenient to place these in compensated expenditure share form:  $w_i = (p_i/e)(\partial e / \partial p_i)$ , where  $w_i$  is the share of expenditure on  $i$ . Next, (3) can be solved for  $u$  using  $e = y$ , expenditure = income. The resulting indirect utility substituted into the compensated share equations yields the uncompensated expenditure share equations:

$$(4) w_i = \alpha_i + \sum_{j=1}^n \gamma_{ij} \log p_j + \beta_i \log(y/P),$$

where  $P$  is the true cost of living index

defined by

$$(5) \log P = \sum_j \alpha_j \log p_j + \frac{1}{2} \sum_i \sum_j \log p_i \log p_j.$$

Deaton-Muellbauer argue that  $P$  is usually closely approximated by standard indices. The restrictions implied by consumer theory are

$$(6) \gamma_{ij} = \gamma_{ji}, \quad \text{symmetry;}$$

$$(7) \sum_{i=1}^n \alpha_i = 1, \quad \sum_{j=1}^n \gamma_{ij} = 0, \quad \sum_{j=1}^n \beta_j = 0, \quad \text{homogeneity;}$$

$$(8) \{k_{ij}\} = \{-\delta_{ij}w_i + w_iw_j + \beta_i\beta_j \log y/P\}, \quad \text{negative semidefinite, concavity.}$$

In (8),  $\delta_{ij}$  is the Kronecker delta. The matrix  $k = \{k_{ij}\}$  is a simple transform of the Slutsky matrix, with the same properties.

Equation (4) in its stochastic form is fitted to 1964–79 U.S. quarterly data. A nine-equation set of  $w_i$ s is fitted to the logs of a set of fifteen cheese prices (including domestic types), a general price index for food, and a "real food and beverages" expenditure term  $y/P$ . It is convenient to normalize the price data by division by the arithmetic mean. The transformed log price data is then all zero at the point of arithmetic means. In the base case estimation, symmetry and homogeneity are imposed on (4). Concavity (for the nine imported cheese prices) is imposed at the point of means and holds in small region about it as discussed in my earlier paper. The results are reasonably "good." The main sources of possible specification error are in aggregation over consumers and over cheeses. The data do not permit an attack on these problems. To give some feel for the demand structure that results, Table 1 presents point estimates of compensated price elasticities. They are defined by

$$(9) e_{ij} = -\delta_{ij} + w_j + \frac{\gamma_{ij}}{w_i} + \frac{\beta_i\beta_j \log y/P}{w_i},$$

where  $\delta_{ij}$  is the Kronecker *delta*. The elasticities are evaluated at the point of means of the shares. A reader skeptical of the econometric methods used is free to regard these and the underlying parameters as plausible guesses to be used in simulation.

The estimated imported cheese demand functions and the symmetry restrictions of the expenditure function ( $\gamma_{ij} = \gamma_{ji}$ ) permit a complete account of the effect of a change in import policy. All relevant parameters of the expenditure function are known, as are the relevant cheese demand parameters. The analysis of Section I derives the efficient policy as being a uniform tax that would achieve the same aggregate quantity of constrained cheese. The estimated demand functions evaluated at the point of means can be used to solve for the efficient tax. A welfare analysis can then be carried through, based on the consequences of the change in the vector of constrained imported cheese prices.

#### IV. The Welfare Loss of Inefficient Dairy Quotas

The model used to evaluate the welfare effects of the change from quotas to the efficient tax system is standard. The changes are measured in 1) the representative (hence aggregate) consumer's expenditure,<sup>4</sup> 2) the

government's tax receipts, and 3) the quota license holder's loss of rent. Ordinarily, we would need to add in the change in income from production, but it is assumed domestic product prices are constant. For noncheese products, this is because it is assumed the changes in imported cheese prices have negligible effect on demand. For all domestically produced cheese, it is assumed for convenience that the government supports the price by purchases.

In practice government price support is given only for American-type cheese. The effect of assuming support for non-American-type cheese is to wash out some second-order effects on welfare via domestic product price changes. These have negligible first-order effects, since with supply equal to demand, the expenditure effect and production revenue effect cancel. I make this assumption to avoid what might be an inappropriate use of the implicit model of domestic supply. I report below on both American-type and total support payment changes.

Formally, the expenditure function may be written as  $e(p, s, u)$ , where  $p$  is the vector of domestic prices for constrained goods,  $s$  is the vector of domestic prices for unconstrained goods, and  $u$  is the parameter utility level. The vector  $s$  is made parametric either by: (a) the small country assumption for traded goods other than cheese, (b) standard partial equilibrium "smallness" arguments

<sup>4</sup>A superior alternative is available. Equation (3) can be solved for  $u$  with  $e = y$ , with  $u$  now indirect utility. The result can be substituted back into (3), which now becomes the (log of) income compensation function, or (log of) the money metric of utility change,  $\log e(p^0, u(p, y))$ , where  $p^0$  is a base price vector and  $p$  is an alternative price vector. This is the ideal welfare measure. For the case studied, movement of  $u$  is

guaranteed to be trivial and it is simpler to keep it constant. Thus we use the expenditure function (3) as the basis of welfare calculations (which corresponds to use of compensating rather than equivalent variations).

with respect to nontraded goods, or (c) government floor price support purchases for domestic cheese products displaced by import price changes. The vector  $p$  is built up from foreign prices:

$$(10) \quad p = p^* + (\text{margins}) + t,$$

where  $p^*$  is the parametric foreign price vector,  $(\text{margins})$  is the assumed parametric vector of distribution margins, and  $t$  is the tax-cum-quota-rent vector. If  $p^0$  and  $p^1$  are two vectors created by alternative restriction policies, the change in expenditure is

$$(11) \quad \Delta e = e(p^1, s, u) - e(p^0, s, u).$$

The change in quota rent is simply the original demand times the quota rent:  $\partial e / \partial p \cdot t$  in the case where there was no initial tax on imports. In practice, there is in fact a portion of  $t$  which is a tax,  $t_g$ , so the actual rent lost is

$$(12) \quad \Delta \text{rent} = \frac{\partial e(p^0, s, u)}{\partial p} \cdot (t - t_g).$$

Now I account for government support payments. The displaced domestic demand is replaced by government purchases. Let  $s_d$  denote the supported products price vector, where  $s_d$  is composed of some element of  $s$ . The change in support payments

$$(13) \quad \Delta \text{support} = \left[ \frac{\partial e}{\partial s_d}(p^1, s, u) - \frac{\partial e}{\partial s_d}(p^0, s, u) \right] \cdot s_d,$$

where  $\partial e / \partial s_d$  is the compensated demand vector for supported products. Below I present two measures for (13). One is the American-type cheese support payments—the only cheese so supported in reality. The other is the assumed support payments for all domestic cheese in the quota-protected categories.

The first variant on (13) is a lower bound for actual support payment changes, since additional small changes in demand for other supported dairy products might be expected.

The second minus the first is an upper bound for additional welfare loss, due to changes in other domestic cheese prices, since cheeses other than American-type are not supported. It should ordinarily far exceed the actual small secondary effect we are neglecting.

Finally, I account for changes in tariff revenue. On the group of constrained cheeses, the revenue is based on the common scalar efficient tax  $t^*$  solved for to satisfy the constraint:

$$(14) \quad \frac{\partial e}{\partial p}(p^* + (\text{margins}) + t^* \iota, s, u) \cdot \iota = \bar{Q},$$

where  $\iota$  is the vector of ones. Revenue is collected in the amount  $t^* \cdot \bar{Q}$ . From this must be deducted the revenue previously collected by the government with its taxes on this group of cheese:  $\partial e / \partial p \cdot t_g$ , where  $t_g$  is the initial specific tax vector (converted from the ad valorem actual tax at the point of mean prices). Thus the change in revenue is

$$(15) \quad \Delta \text{revenue} = t^* \bar{Q} - \frac{\partial e}{\partial p}(p^0, s, u) \cdot t_g.$$

Note that (15) neglects the change in tariff revenue on the non-quota-constrained imported cheeses. This is done on the principle that the government budget constraint is supposed to be irrelevant, although I have kept track of  $\Delta \text{support}$ .<sup>5</sup> The amounts involved are small, in any case.

I report two welfare measures below. Gross welfare is the logically consistent measure corresponding to the theoretical model. It neglects  $\Delta \text{support}$ .

<sup>5</sup> If government revenue is made to matter, a revenue constraint is added to the problem, and in the optimal solution a Ramsay price element is added to the uniform part of the optimal tax, as noted in Section I. It should be noted that another version of the problem kept the existing ad valorem taxes as given politically, and optimized the quota system analogously to the procedure above. This procedure worked nearly as well as the solution reported. This is not surprising in view of the low level and low dispersion of the ad valorem tariffs.

(16)  $\delta$  gross welfare

$$= -\Delta e - \Delta \text{rent} + \Delta \text{revenue}.$$

Net welfare subtracts from this the change in support payments on American-type cheese.

The efficient tax and its welfare consequences in (12)–(15) are calculated using the parameter estimates detailed in my 1983 paper. The procedure can be performed at any data point. I restrict attention primarily to the point of sample means, but discuss briefly the evaluation of extremal values. In the estimated AIDS system (4), the income terms  $\beta_i$  are effectively zero, so that we may impose homothetic preferences for evaluation purposes.<sup>6</sup> The uncompensated share equations (4) are equal in this case to the compensated share equations. I solve them for quantity demanded in the six quota-constrained categories. The government's noneconomic constraint is to hold aggregate imports across the six cheeses to the given sample mean quantity. We know the efficient solution requires a uniform specific tax  $t$ . The new domestic price for import  $i$  will be  $\hat{p}_i + t^*$ , where  $\hat{p}_i$  is the margin augmented foreign price, or free-trade price. I solve for the optimal tax  $t^*$  in

$$(17) \quad \bar{Q} = y \sum_{i \in QR} 1/(\hat{p}_i + t) \\ \times \left\{ \alpha_i + \sum_{k \in QR} \gamma_{ik} \log((\hat{p}_k + t)/p_k^0) \right\}.$$

The term in curly brackets is the new expenditure share for import  $i$ ,  $i \in QR$ . The  $QR$  is the index set for constrained cheeses, and  $\bar{Q}$  is the given sample mean aggregate quantity. Operations outside the curly brackets convert shares to quantities, and aggregate. Inside the brackets,  $p_k^0$  is the sample mean (quota regime) price. Its presence is necessitated by the econometric procedure of using sample-mean-scaled prices. The great convenience of this method is that other

arguments of (4) are zeroed out in evaluation at the sample mean (all right-hand side data are scaled by the sample mean and  $\log(x/\bar{x}) = 0$  at  $x = \bar{x}$ ).

Equation (17) is well behaved as a function of  $t$  at the sample means point, and Newton's method converged very quickly. For evaluation away from the point of means, (17) is somewhat more complex in form, and for extremal values of  $p_k$  has possible multiple roots (one case was discovered). This difficulty is related to the problem of non-concavity of the estimated  $e(p, u)$  at extreme values of  $p$ .<sup>7</sup> I restrict primary attention to the point of means for this reason, but report results at other data points because the extremal price distortions are precisely where the quota inefficiency ought to be greatest.

From evaluation of (17), the resulting new domestic price vector  $\{\hat{p}_i + t^*\}$  for six categories is then plugged into the expenditure function (3). The relative change in expenditure is obtained by subtracting the log expenditure at the initial point from that at the new point, then exponentiating. The absolute size is obtained by multiplying by base expenditure. Making use again of the zeroing-out property of evaluation at the point of means, I report the application of (11):

$$(18) \quad \Delta e = \exp \left[ y \sum_{i \in QR} \left\{ \alpha_i \log((\hat{p}_i + t^*)/p_i^0) \right. \right. \\ \left. \left. + \frac{1}{2} \sum_{k \in QR} \gamma_{ik} \log((\hat{p}_i + t^*)/p_i^0) \right. \right. \\ \left. \left. \times \log((\hat{p}_i + t^*)/p_k^0) \right\} \right].$$

<sup>7</sup>The efficient quota problem (1) has a unique global optimum defined by the equations (2), the first-order conditions. Equation (17) is the sum of the rows of the inverse of system (2), hence need not yield a unique  $t^*$ . Among its solutions must lie the optimal tax. Note that the derivative of (17) with respect to  $t$  is ordinarily negative, the more so as own-effects predominate. "Good behavior" has the derivative negative in the relevant range, thus yielding a unique solution. Nonconcavity evidently exacerbates the "bad behavior" problem, since it is associated with prominent cross effects.

<sup>6</sup>One income elasticity differs statistically significantly from unity in the third place to the right of the decimal point.

Government tax revenue is lost by doing away with the existing ad valorem taxes, and gained by the new specific tax. The new revenue for the six categories is  $t^* \cdot \bar{Q}$ . The revenue lost is subtracted from this, so the application of (15) is

(19)  $\Delta \text{revenue}$

$$= t^* \bar{Q} - y \sum_{i \in QR} \frac{\tau_i}{1 + \tau_i + \text{cif}_i + \text{whl}} \alpha_i,$$

where  $\tau_i$  = ad valorem tariff rate on  $i$ , and other variables are cif and wholesale margins, respectively. In (19) I make use of evaluation at the point of means, so  $\alpha_i$  is the relevant share of imported cheese. I divide by  $1 +$  the tax rate plus the cif percent markup (cif) + the wholesale percent markup (whl) to convert the domestic value in  $\alpha_i$  into a foreign f.o.b. value.

I calculate  $\Delta \text{support}$ , the application of (13), using evaluation at the simple mean, as

(20)  $\Delta \text{support}$

$$= y \sum_{j \in S} \sum_{k \in QR} \gamma_{jk} \log((\hat{p}_k + t^*)/p_k^0),$$

where  $S$  is the set of supported cheeses and other variables are previously defined.

Below, the gross welfare measures represent the pure logic of quota inefficiency measurement; the net measures have increases in cheddar support payments subtracted out. These overestimate the change the government would actually experience, since aged cheddar is not supported. I also report a support payment change on the assumption that *all* domestic cheese displaced must be purchased by the government.

The net welfare figure presented below is biased very far downward, the gross welfare figure is biased somewhat upward by its failure to account for the displaced domestic cheese not subject to support payments. Presumably this will cause changes in the price of domestic cheese, the welfare consequences of which will have to be traced through. For the efficient tax solutions the bias is very minor, since the displacement is under 3 percent of the total market in each cheese.

For the free-trade solutions, the case is more serious (displacement of 9 and 19 percent in the two cases below), and for cheddar in particular the bias will be substantial (displacement of 19 and 39 percent). In the absence of a model of domestic cheese production there was little to be done about this. It was not significant to the study, since the free-trade solutions are produced primarily to scale the efficient tax solutions of interest.

The final category in the welfare calculation is the loss of quota rent. The entire rent change is treated as a loss, though some rent probably goes to foreigners or is dissipated in rent-seeking activity.

Two cases are detailed below. In one, the allocation of country imports does not shift to low-cost producers; in effect there is only one representative exporter for each cheese. The average base-period f.o.b. unit value is thus used to form  $\hat{p}_i$ . The other case uses a conservatively picked lower-cost producer as the importer. The new import price was far from the lowest and came from a supplier with deep markets and substantial share already (for example, New Zealand or West Germany). The new lower  $\hat{p}_i$  then serves as the base for recalculating all previous steps. This procedure inevitably has considerable danger of (dis-)aggregation bias. For the composite SITC 0240025, Romano-Parmesan-Provolone, etc., no such reallocation is allowed. For the other categories, the gain in realism appears worthwhile. For one category, Swiss, I have domestic price series for Finnish, Austrian, and Swiss origin. The latter commands about a 10 percent premium. The cif import unit values in these categories diverge by 30 percent or more. Thus there is clearly a country reallocation gain to be reaped.

As a basis for the commodity reallocation gains, Table 2 presents the sample mean ad valorem tariff rates and the mean ad valorem equivalent quota margins for the six constrained categories. The sample mean foreign port values of the various imported cheeses range from .6 to 1.6, so Table 2 obviously implies an inefficient specific tax equivalent. At most data points, the quota margins show *much* wider variation over categories than at the point of means shown in

TABLE 2—MEAN POLICY DISTORTIONS ON  
IMPORTED CHEESE, 1964–79

<sup>a</sup>Aggregating biases these estimates downward.<sup>b</sup>No domestic price of imported cheese available. Estimate constructed by applying the mean of markups of a large number of components from other categories.

the table, so greater efficiency gains can be expected.

The results of efficient allocation are in Tables 3 and 4. Table 3 has the optimal specific tax (the solution of (17)), and the unscaled amounts (in millions of base dollars). A negative sign is a fall in the category whether increasing or decreasing welfare. Since imported cheese is small relative to *GNP* or even advanced war equipment, the numbers in Table 3 are not impressive. They are supplied mainly to allow alternative treatment by the reader of dubious categories like support and rent.

Scaling the absolute magnitude of changes is critical to seeing their importance. One scale used is base expenditure on the six imported constrained cheeses. The other scale used is the welfare change implied by going to free trade (redo the calculations above with  $t = 0$ ).

Two appropriate scales are in Table 4. The first four columns express the savings as a proportion of base expenditure on the six cheeses. Columns 2 and 4 contain the net and gross welfare proportionate changes implied by free trade. The percentages in columns 1 and 2 are fairly impressive. My best guess is that at the point of means, an efficient tax saves us over 15 percent of base expenditure (row 2, column 1 of Table 3). Standard triangle welfare loss measurement seldom turns up relative gains of more than 1 percent.

Perhaps the most revealing measure of relative inefficiency of the quota is in column 5,

the result of dividing column 1 by column 2. For the two cases shown, the number says that efficient taxation takes us 10 and 30 percent, respectively, of the way back to free trade.

Table 5 contains percentage changes in imported cheese consumption in the efficient tax solutions. Short of implementing an efficient tax, the numbers in Table 5 could be used to guide a reallocation of quota licenses. Quota administrators might in fact not be surprised at the numbers in Table 5, since they are linked to the size of current sample mean quota margins and tariffs. Compare Tables 5 and 2. In the more extreme data points, the quota margin variations cause less obvious substitution patterns to be optimal.

The most disappointing result of Tables 2 and 3 is the small gross welfare gain derived by going to the efficient tax without supply reallocation. This is the pure-differentiated-product" effect (though the gain from country reallocation operates partly through the differentiated product effect). Only about 1/4 of 1 percent of base expenditure is saved by efficient allocation. If evaluation is done at other data points, however, this figure rises to over 2 percent at the maximum. The mean of all gross welfare efficient tax gains (as a percent of base expenditure) is .0044, with a standard deviation of .0043. Over 10 percent of the evaluations yield gross welfare savings in excess of 1 percent of base expenditure. Interestingly, extreme data points also frequently change the sign of net welfare changes. The reason is that support payments often drop rather than rise due to substitution effects. The mean net welfare change as a percent of base expenditure is .012 with a standard deviation of .14. The maximal value of the relative net welfare change is .41 and the minimal value  $-.39$ . More could be made of these extreme values were it not for doubts about their reliability due to the estimated demand system being moved outside the reasonable approximation region.

This brings up the important general issue of sensitivity of results to the estimation of the demand system, especially to the "concavifying" restrictions. As discussed in my earlier paper, concavity was imposed by set-

TABLE 3—EFFECT OF SWITCH TO EFFICIENT TAX ON CONSTRAINED CHEESE, SAMPLE MEAN POINTS (in millions of dollars)

Note: Percent changes in consumption.

ting linear constraints which were incrementally tightened. Tables like 3 and 4 were generated automatically for a large number of concavifying restriction values. The numbers in especially the first 3 rows of Table 4 were highly robust with respect to these changes. It is notable that this statement

applies even to evaluations where concavity at the point of means was not attained. Another check on sensitivity is afforded by using the Cobb-Douglas limiting case of the AIDS. The Cobb-Douglas parameters are the mean shares. It implies price elasticities which differ substantially from the point estimates of AIDS elasticities at the point of means. Compare the 9 rows and columns of Table 1 with minus the identity matrix, which closely approximates the compensated Cobb-Douglas price elasticity matrix given the smallness of shares. Net and gross welfare changes are approximately equal for the Cobb-Douglas, so we check the sensitivity of gross welfare changes to the functional form. When analogous calculations are carried through to produce the upper left cell of Table 4, gross welfare inefficiency relative to base expenditure, with no supply reallocation, the corresponding number is .0013, versus the table's .0028. With reallocation,

the Cobb-Douglas gain is .147 of base expenditure vs. .152 in Table 4. The data reject the Cobb-Douglas model very strongly (the equation  $R^2$ s in the AIDS average over .50). Nevertheless, the Cobb-Douglas is so familiar and easy to use that it makes a convenient benchmark. A bias factor so small when even so gross a misfit as the Cobb-Douglas is imposed suggests that the underlying inefficiency is indeed substantially accurately measured by the methods of this study at the point of means. Something like this relationship is maintained even at more extreme values of the data.

The impressive magnitudes in Tables 4 and 5 validate the main proposition of this study. Quota systems on heterogeneous commodities are likely to add substantially to the inefficiency of protection. Subsidiarily, the results bear out claims that any welfare loss measure will be greater the greater the disaggregation. Painful as it may be, commodity detail is strongly indicated for studies of protection. Finally, the results together with difficulties experienced in achieving comparability of data argues strongly that government statistical bureaus should collect data on quota categories automatically in the form required to assess incidence.

# Testing for the Effectiveness of Wage-Price Controls: An Application to the Carter Program

By JOHN B. HAGENS AND R. ROBERT RUSSELL\*

During the last twenty-two years, income policies have been in effect in the United States more than half the time. The Kennedy-Johnson wage-price guideposts lasted almost six years, although they were tattered and torn by the time they were abandoned in 1967. The Nixon Administration's Economic Stabilization Program (ESP)—the only peacetime mandatory controls program in the United States—lasted four years, although the second half of the program (Phases III and IV) was a period of decontrol. The Carter Administration's Pay and Price Standards Program lasted a little more than two years, although the second year was one of thinly disguised decontrol.

It is not unlikely that another incomes policy will find its way into a government anti-inflation policy package sometime in this decade. The popular press regularly runs editorials and guest articles on the need for an incomes policy, and some presidential aspirants have incorporated incomes policies (especially tax incentive programs) into their informal platforms.

Unfortunately, the economics profession offers little guidance to policymakers about the efficacy of such programs. Diametrically opposite conclusions are reached by arm-chair reasoning (which is often predicated on strongly held ideological preconceptions), and the results of empirical tests too often are conflicting, ambiguous, or inconclusive.

These conflicting empirical results are partly attributable to the notorious non-robustness of wage and price equations (and

of other models of inflation, such as extreme-monetarist and ARIMA models),<sup>1</sup> but part of the problem is the paucity of thought that has gone into the formulation of the hypothesis to be tested. The standard approach is a test for the statistical significance of the estimated coefficient of an "on-off" intercept dummy variable. There are, however, many ways in which an incomes policy might conceivably affect the structure of an inflation model. Articulation of these different possible effects can be found in policymakers' justifications of particular incomes policies—for example, bringing wage demands into line with productivity growth, shifting the (short-run) Phillips curve downward, changing the tradeoff between unemployment and inflation (i.e., changing the slope of the short-run Phillips curve), retarding inflationary expectations, breaking the wage-price or the wage-wage spiral, and preventing extraneous shocks from getting built into the wage-price process. These alternative versions of the objectives of incomes policies have profoundly different implications for the effect on the structure of a model of the inflation process. Yet virtually no attention has been paid to the diversity of potential effects of such policies.

The purpose of this paper is to convert these justifications into testable hypotheses. We adopt a model of the type typically used to test for the effects of controls programs: a price equation based on a markup over costs and a wage equation that is consistent with but does not necessarily imply the natural-rate hypothesis.

\*Chase Econometrics, 150 Monument Rd., Bala Cynwyd, PA 19004, and Department of Economics, New York University, New York, NY 10003, respectively. We thank Michael Holdowsky, an anonymous referee, and especially Rob Engle for helpful comments, and Chase Econometrics and C. V. Starr Center for Applied Economics for technical support.

<sup>1</sup>The robustness of the recent new-neoclassical models of inflation is a currently contentious issue, but these models have not yet been employed to test for the effect of controls.

While the focus of our analysis is the Carter program,<sup>2</sup> we also provide additional tests of the effectiveness of the guideposts and the ESP. Our results modify slightly previous conclusions about the ESP: in our view, the catch-up occurred not after the controls were lifted (as Robert Gordon, 1975, and Alan Blinder and William Newton 1981, conclude) but, rather, during the period of decontrol (Phases III and IV). We also show that correction of a specification error in the wage equations typically used in the analysis of controls programs substantially reduces previous estimates (for example, George Perry, 1970, 1980) of the effect and statistical significance of the Kennedy-Johnson guideposts program.

Our principal conclusion about the Carter program is that the roughly concurrent 1979–80 energy-price explosion was not passed through to wages, and hence the general price level, in the usual manner. Whether the moderate behavior of labor costs during this era of double-digit inflation was the result of the Carter program remains an open question.<sup>3</sup>

Section I formulates hypotheses about the effects of wage-price controls in the context of a simplified model of the wage-price process. Section II presents our empirical results.

## I. Formulation of Hypothesis Tests

### A. A Simplified Wage-Price Model

A simplified two-equation model of the wage-price process is as follows:

$$(1) \quad \dot{W} = a_0 + a_1 L(\dot{P}) + a_2 (U - \bar{U});$$

<sup>2</sup>For an extensive description and evaluation of this program, see the final report of the Council on Wage and Price Stability (1981). (We should alert readers that we participated in the administration of this program and the writing of the final report.)

<sup>3</sup>A finding of effectiveness in retarding the inflation rate is not, of course, an endorsement of an incomes policy: against these benefits, one would have to weigh the (unfortunately nonquantifiable) costs of administrative burden and market distortion.

$$(2) \quad \dot{P} = b_0 + b_1 (\dot{W} - R) + b_2 \dot{M}.$$

The wage equation expresses the percentage rate of change of hourly labor compensation,  $\dot{W}$ , as a linear function of a distributed lag on past percentage rates of change of consumer prices,  $L(\dot{P})$ , and the disparity between the actual and natural unemployment rates,  $U - \bar{U}$ .

The distributed lag on past inflation rates is generally interpreted as a reflection of adaptive expectations of future inflation rates. In this interpretation, the coefficient  $a_1$  would be equal to 1.0 in the absence of money illusion (the weights in  $L(\dot{P})$  are normalized to sum to one).<sup>4</sup> We prefer to interpret the inclusion of past inflation rates in the wage equation as reflecting the backward-looking efforts of workers to make up for past inflation, not only to avoid getting sidetracked into the raging debate on the appropriate formulation of an expectations hypothesis, but more fundamentally because we believe that this is a more realistic representation of the formation of wage demands and of compensation practices. Formal cost-of-living adjustment clauses are explicitly backward looking, with today's adjustments depending on past inflation rates. In addition, formal annual pay plans in the non-union sector are typically calibrated to the past year's increase in the cost of living. In testing for effects on expectations, however, we interpret  $L(\dot{P})$  as adaptive expectations. In any event, the above specification of the wage equation cannot discern between forward-looking and backward-looking hypotheses about the determination of wage changes.

The second explanatory variable in equation (1) is a measure of labor-market disequilibrium. Measuring labor-market conditions by the disparity between the actual and natural unemployment rates incorporates into the

<sup>4</sup>Of course,  $a_1 = 0$  implies money illusion only if expected inflation is identically equal to  $L(\dot{P})$ —i.e., that expectations are “extrapolative” as in Philip Cagan (1956) rather than “regressive” (predicated on a “normal” price level), as in Robert Lucas and Leonard Rapping (1969, p. 732).

model the intertemporal shift of the short-run Phillips curve attributable primarily to demographic changes in the labor force (which, until recently, have raised the natural unemployment rate). The coefficient,  $a_2$ , is the slope of the short-run (one-period) Phillips curve—the short-run tradeoff between unemployment and wage inflation (abstracting from one-period feedbacks between the wage and price equations).

So long as  $a_1 = 1$ , the constant term,  $a_0$ , can be interpreted as equilibrium wage growth—that is, the steady-state growth of real wages with equality of the natural and actual unemployment rates. (If we let  $\dot{P}$  equal a constant,  $a_1 = 1$ , and  $U = \bar{U}$ , equation (1) becomes  $\dot{W} - \dot{P} = a_0$ .) In a regime of constant factor shares, the equilibrium wage growth is equal to the trend growth of labor productivity.

A fully specified wage equation includes a number of other variables, including changes in the minimum wage rate and employment taxes.

The price equation (2) is a fairly standard mark-up formula. The percentage rate of increase of prices is a function of the growth of unit labor cost at trend productivity growth,  $R$ , and the percentage rate of change of exogenous materials prices,  $\dot{M}$ . In this specification, capital costs are omitted; hence, the estimated values of  $b_1$  and  $b_2$  should approximately equal the shares of labor and materials in total cost divided by the complement of the capital share. In a regime of approximately constant secular factor shares, the constant term should be close to zero.

One can include capital costs (in which case the equation comes close to being an accounting identity) and a measure of disequilibrium in product markets, but these variables typically have little explanatory power (presumably because of difficulties of measuring capital costs and because inventory fluctuations provide a buffer between market disequilibrium and prices). A variable that typically does have explanatory power is the deviation between actual and trend productivity growth, reflecting the effect of current as well as trend changes in unit labor costs.

## B. Hypothesis Tests

Wage-price models of the above type have been used by a number of investigators to test the effectiveness of incomes policies in slowing the rate of inflation. The usual approach attempts to incorporate the program directly into the model by including a variable that represents it. Typically this is an intercept dummy variable, equal to zero when the program is not in effect and equal to one when it is. The dummy variable can enter the wage equation, the price equation, or some quasi-reduced form (typically with a lagged dependent variable in order to circumvent the problem caused by the infinite lag in the true reduced form). As William Nordhaus (1975) has complained, this approach is extraordinarily unimaginative.

Some investigators have improved upon the straight dummy-variable approach by using multiple dummy variables to reflect different stages of a program or a postcontrols catch-up. The most sophisticated attempt to model controls is that of Blinder and Newton, who construct a variable representing the share of the (nonfood, nonenergy) Consumer Price Index (*CPI*) covered by the ESP during each month of the program. This is an improvement on the typical approach, but it still presumes that the program affects the price equation only through shifts in the intercept term (though by varying amounts each month).

More important, it is questionable whether a coverage variable adequately captures the characteristics of the program. A much more important consideration than coverage is the tightness of the standards and the degree of enforcement. More significant than coverage in the ESP is the distinction between the two freezes, the period of mandatory but more flexible controls (Phase II), and the periods of "voluntary" controls (Phases III and IV). Similarly, in the Carter program, coverage was essentially unvarying, but there was nevertheless a big difference between the first and second years of the program. During the second year, the newly established Pay Advisory Committee substantially relaxed the wage standard and also blocked

enforcement efforts by the Council on Wage and Price Stability. Finally, Perry (1970, 1980), in the most thorough econometric analysis of the Kennedy-Johnson guideposts, phases a dummy variable in and out over the 1962–67 period to reflect varying degrees of intensity despite the fact that coverage was invariant. Thus, coverage typically is not a good indicator of the effectiveness of the design and institutional characteristics of a program. Appropriately constructed dummy variables can usually capture the typically discrete changes in these characteristics.<sup>5</sup>

An incomes policy could conceivably affect the structure of the wage-price process in a number of ways. Some or all of the coefficients of the explanatory variables in either the wage equation or the price equation might change. Moreover, coefficient changes may vary over time. Since the number of possible hypothesis tests is limitless, some thought must be put into determining which hypotheses are worthy of investigation.

1. *Bringing Wage Demands into Line with Productivity Growth.* The typical intercept-shift hypothesis test is justifiable because one commonly stated objective of incomes policies is to educate the public about the relationships between productivity growth, inflation, and income shares. This was the avowed purpose of the Kennedy-Johnson guidepost program, where wage demands were to be brought into line with the trend rate of growth of labor productivity. If  $a_0$  in the wage equation exceeds trend productivity growth, there is an inflationary bias built into the wage equation.

Thus, an intercept dummy can be used to test the hypothesis that an incomes policy depressed the “productivity factor” in wage settlements.<sup>6</sup> Unfortunately, the intercept

dummy tests that have been employed by most investigators are not appropriate because of misspecification of the wage equation, since the trend rate of growth of productivity has been falling over time. If the intercept dummy and the missing productivity variable are correlated, the estimated coefficient of the dummy variable is biased.

2. *Changing the Inflation-Unemployment Tradeoff.* Much of the rhetoric surrounding incomes policies focuses not on shifting the Phillips curve—the effect of an intercept shift—but rather on changing its slope. This was especially notable in the early justification by the Carter Administration, where much of the emphasis was on “...creating an environment in which the effect of fiscal and monetary restraint on unemployment and real growth will be minimized and the effect on inflation will be maximized” (Council on Wage and Price Stability, 1979, p. ix). In this characterization, the incomes policy is intended to operate on the coefficient  $a_2$  in equations (1) and (3). One can test this hypothesis by the incorporation of an interactive variable for the incomes policy,  $I$ :

$$(3) \quad \dot{W} = a_0 + a_1 L(\dot{P}) + (a_2 + \hat{a}_2 I)(U - \bar{U}).$$

This approach, however, is simplistic; presumably, while the objective of an incomes policy may be to steepen the slope of the short-run Phillips curve for *increases* in the unemployment rate, steepening the slope for *decreases* in the unemployment rate would be perverse. The latter effect would imply that the policy exacerbates the inflationary effects of stimulative fiscal or monetary policies. Thus, one might wish to test for an asymmetric effect on the slope of the short-run Phillips curve. For example, the program might increase its slope for higher unemployment rates but leave the slope unchanged for lower unemployment rates. Alternatively, one might hypothesize that the incomes policy would improve the tradeoff in both directions, mitigating the inflationary effects of expansionary policy.

Tests for such asymmetric effects can be formulated, but they require observations during incomes-policy periods with both ex-

<sup>5</sup>As Jon Frye and Gordon (1981) show, a pair of dummy variables does as good a job of reflecting the effects of ESP as the Blinder-Newton coverage variable.

<sup>6</sup>Similarly, an effort by employers to expand profit margins (thus increasing capital's share of total income) would be reflected by a positive value of the constant term,  $b_0$ , in the price equation. Thus, a programmatic intercept dummy in the price equation can be used to test the hypothesis that a price guideline brought profit margins into line with labor and materials-cost growth.

pansionary and contractionary fiscal and monetary policies. Unfortunately, during all three of the incomes policies adopted in the United States in the last two decades, fiscal and monetary policies were primarily expansionary; hence, it is probably not possible to test for a change in the slope of the short-run Phillips curve for higher levels of the unemployment rates.

3. *Deflating Inflationary Expectations.* Perhaps the most common justification for incomes policies (or at least the most respectable among professional economists) is the attempt to deflate inflationary expectations.<sup>7</sup> Interpreting  $a_1 L(\dot{P})$  in equation (1) as an expectations-formation mechanism, we can test for this phenomenon by estimating the effect of a program on  $a_1$  or the parameters of  $L(\dot{P})$ . The latter changes the pattern of adaptation to past inflation rates, whereas the former shifts the lag parameters proportionately.

4. *Insulating the Economy from Shocks.* In 1979, as monetary accommodation of the worldwide oil-price shock allowed domestic inflation rates to hit record peacetime highs, the avowed objective of the Carter Administration's program changed. The original goal of price deceleration was abandoned and replaced by the goal of preventing the energy-price explosion from getting built into the wage-price spiral. Holding firmly to the 7 percent pay guideline, the Carter Administration repeatedly stressed the temporary nature of the shock and the futility of trying to recover, by the escalation of wages, the real income transferred to oil-exporting countries. Quantitative estimates of the direct contribution of the energy-price explosion to the inflation rate were repeatedly underscored.

Testing for the success of an incomes policy in insulating an economy from international price shocks is less straightforward than the above tests for parameter shifts. The test is

not for an effect on the structure of the wage-price model, but for an effect on agents' perceptions of the variables. One possible formulation of this test in the wage equation is

$$\dot{W} = a_0 + a_1 \sum_i \lambda_i \dot{P}_{-i} + \alpha \sum_i \lambda_i S_{-i} + a_2 (U - \bar{U}),$$

where the  $\lambda_i$  are the coefficients of the lag distribution,  $L(\dot{P})$ , the subscript  $-i$  denotes an  $i$ -period lag,  $\alpha$  is a parameter, and  $S$  is the shock component. In particular, the shock component would be equal to zero in all periods except the period of the shock (an admittedly subjective determination), and it would be equal to the contribution to the inflation rate during the shock period (see Section II for a specific application). If the shock component of inflation were not passed through to wage inflation in the usual manner, then  $\alpha$  would be negative. Of course, the maintained hypothesis is that any non-pass-through is attributable to the incomes policy. At a minimum, this requires rough concurrence of the shock and the program.

## II. Empirical Results

Using quarterly U.S. data from the second quarter of 1954 (1954:II) to the second quarter of 1983 (1983:II), we test several of the foregoing hypotheses regarding the effectiveness of the Carter Administration's Pay and Price Standard Program. Precise definitions of the variables used and citations of the sources of data are in the Appendix.

### A. Wage Equations

Table 1 contains the parameter estimates of seven different wage equations. In each, the dependent variable is the percentage change in total labor compensation per hour.

Equation (1.1) incorporates intercept shifts for each of the three controls programs in effect during the sample period. The estimated constant term of 3.2 is an estimate of the equilibrium rate of wage growth. This estimate is precisely equal to the Kennedy-

<sup>7</sup>The Council on Wage and Price Stability stressed the attempt to "...moderate the inflationary expectations of business and worker..." (1979, p. ix).

<sup>b</sup>  $L(\cdot)$  connotes a third-degree polynomial distributed lag, with the far endpoint constrained to zero. The lag length is 12 quarters, starting with the variable lagged 1 quarter.

Johnson wage guidepost, an explicit estimate of equilibrium (noninflationary) wage growth at that time.

The estimated coefficient of the disparity between the actual and natural unemployment rates,  $U - \bar{U}$ , is highly statistically significant and is consistent with other esti-

mates of the short-run wage-unemployment rate tradeoff (see, for example, Gordon, 1981; Arthur Okun, 1975; and Perry, 1980). It implies that a one-percentage-point increase in the unemployment rate lowers the rate of wage inflation by half a percentage point. In other words, to lower the rate of wage infla-

tion by one percentage point in a single quarter, the unemployment rate would have to rise by two percentage points. Of course, a sustained rise in the unemployment rate would have an accumulating effect on the wage inflation rate.

The third coefficient is the sum of the coefficients of the distributed lag on prices. The estimate, 0.64, together with the *t*-statistic, implies statistically significant money illusion and a downward-sloping long-run Phillips curve.

The *DATADUM* variable is simply a dummy variable that corrects for the effect of linking two different wage series.

The fifth explanatory variable reflects the effect of changes in employment taxes. The coefficient implies that, at least in the short run, all of the employer component of a Social Security tax increase is shifted forward (higher prices) and none is shifted backward (lower wages).

The sixth variable is the percentage change in the minimum wage. Although statistically significant, the coefficient is extraordinarily small, implying that a ten-percentage-point change in the minimum wage raises the overall wage level (including fringe benefits) by only two-tenths of one percentage point.

The seventh explanatory variable is an intercept-shift dummy to capture the effect of the Kennedy-Johnson guidepost program. We adopt the approach of Perry (1970, 1980), phasing the guideposts in during 1962 and phasing them out during 1967. The coefficient, which is consistent with Perry's estimate, implies that the guidepost program lowered the rate of wage inflation by one percentage point. Moreover, the estimated effect of the program is statistically significant.

The next two variables, *ESP1* and *ESP2*, are intercept-shift dummies for Phases I and II and Phases III and IV, respectively, of the Nixon Administration's ESP. (Phases I and II were periods of strict mandatory control, whereas Phases III and IV were periods of decontrol.) The two dummy variables divide the Nixon controls program approximately in half; consequently, the two coefficients can be added to obtain a rough estimate of the net effect of the program.

The estimates suggest that the Nixon controls program directly raised wage inflation slightly during the strict control phases and depressed wage inflation during the period of decontrol. This apparent paradox can be explained as follows: the perverse *ESP1* estimate reflects the fact that the lowered price inflation in Phases I and II (documented below) was not translated into a commensurately lower rate of wage inflation, and the negative coefficient on *ESP2* reflects the fact that the *ESP2* price surge (documented below) was not passed through in the form of more rapid wage inflation. In other words, on balance, the program had no effect on wages. In any event, the coefficients on *ESP1* and *ESP2* are not statistically significant.

Finally, the *STANDARDS* coefficient and the associated *t*-statistic are consistent with our impressions formed during our involvement in that program. Specifically, our own impression, based in part on extensive discussions with compensation experts and others in the private sector, was that the program lowered the rate of wage inflation by about one percentage point (the coefficient is  $-0.9$ ); but we did not hold this view with a great deal of confidence (the *t*-statistic is  $-2.3$ ).

The Carter Administration's program passed through two distinctive phases: the year of voluntary yet formal controls that were taken quite seriously by the larger U.S. corporations, and then a year of phased decontrol in the context of deteriorating support for the program. To test the hypothesis that the two phases of the Carter program had dissimilar effects, we introduce in equation (1.2) different intercept dummies for the two phases. Our impression is confirmed both by the larger coefficient and the larger *t*-statistic in the first year of the Carter program, and by commensurately lower estimates for the second year. In fact, these estimates pretty much confirm our view that the program lost its *direct* effectiveness in the second year, although lingering feedback effects from the effectiveness of the first year's program did retard wage inflation in the second year. In the tests that follow, we retain the distinction between these two phases of the Carter program, but similar results are obtained by

leaving out *STANDARDS2* or by combining the two phases as in equation (1.1).

It is our view that the standard wage equations, (1.1) and (1.2), are misspecified. Specifically, as noted above, in a wage-price model with no inflationary bias, the constant term should be equal to the trend rate of growth of labor productivity. The problem is that trend productivity growth has not been constant in the United States. Labor productivity in the private business sector was growing at the rate of about 3 percent in the late 1950's, but fell to 2 percent by the end of the 1960's and to 1 percent by the end of the 1970's.

To correct this misspecification, we replace the constant term with a trend-productivity variable (constructed in the manner of Gordon, 1979) in equation (1.3). The coefficient is close to, but statistically significantly larger than, 1.0, the expected value in an equation without inflationary bias.<sup>8</sup>

The correction of the common misspecification of the wage equation blurs somewhat the distinction between the two years of the Carter program, but the most dramatic changes are in other estimated coefficients of the wage equation. First, the sum of the coefficients of lagged prices is increased from 0.6 in equations (1.1) and (1.2) to 0.8 in equation (1.3), and its statistical significance is enhanced. Apparently, the substantial money illusion implied by equation (1.1) and (1.2) is partly attributable to specification error (inflation and trend productivity growth are negatively correlated over the sample period). Another interesting implication of the correction of the specification error in equations (1.1) and (1.2) is that the estimated

effect of the Kennedy-Johnson guidepost program is reduced by 40 percent and its statistical significance is lowered substantially.

When the specification error in equations (1.1) and (1.2) is corrected, the appropriate test for the effect of an incomes program in lowering the productivity factor in wage equations is a dummy variable that interacts with the trend-productivity variable. In equation (1.4) the Carter Administration Pay and Price Standards Program is incorporated with two interactive dummies: *STANDARDS1* · *R* and *STANDARDS2* · *R*. The estimated effect of the program in this equation is -1.2 percentage points in the first year (the coefficient, -.93, multiplied by the average value of *R* during the year, 1.32 percent) and -1.0 percent in the second year (-0.8 × 1.26)—virtually identical to the equation (1.3) estimates.

Equation (1.5) tests the hypothesis that the Carter program changed the slope of the short-run Phillips curve by incorporating interactive dummy variables, *STANDARDS1* · (*U* -  $\bar{U}$ ) and *STANDARDS2* · (*U* -  $\bar{U}$ ). As neither coefficient is statistically significant, we eschew interpretation. (During the *STANDARDS1* period, there was virtually no variation in (*U* -  $\bar{U}$ ); during *STANDARDS2*, (*U* -  $\bar{U}$ ) jumped from 0.0 to 1.8.)

In equation (1.6), we test the hypothesis that the standards program retarded inflationary expectations, under the assumption that *L*( $\dot{P}$ ) is an indicator of workers' expectations of future inflation. The approach taken is to shift the entire lag distribution by the same proportional factor through the incorporation of interactive dummy variables.<sup>9</sup> For the two phases of the program,

<sup>8</sup>We use the uncentered moments matrix in calculating coefficient estimates and variations of the dependent variable about zero (rather than the mean) in calculating the corrected  $R^2$ s in equations (1.3)–(2.12) of Tables 1 and 2. This results in (relatively) efficient coefficient estimates (since a priori information about the constant term is taken into account) and in corrected  $R^2$ s that necessarily fall between 0 and 1. The corrected  $R^2$ s of equations (1.3)–(2.12) are not, however, comparable to those for equations (1.1) and (1.2). (See, for example, Phoebus Dhyrnes, 1978, pp. 21–24.)

<sup>9</sup>The parameters of the distributed lag and the interactive dummy variables were obtained by iterating between the two. The convergence criterion was  $|\hat{\theta}_j^{\tau} - \hat{\theta}_j^{\tau-1}| < .0001$  for all *j*, where  $\hat{\theta}_j^{\tau}$  is the estimate of the *j*th coefficient from iteration  $\tau$ . To obtain a consistent estimate of the variance-covariance matrix of the estimated parameters, we used the method of artificial regressions suggested recently by Russel Davidson and James MacKinnon (forthcoming). In particular, we regressed the residuals from equation (1.6) on the deriva-

the maintained assumption is that the pattern of the lag distribution is unaffected. The estimated coefficients of equation (1.6) imply that the standards program lowered inflation expectations by 17 percent in the first year and 11 percent in the second. As  $L(\dot{P})$  over the relevant periods averaged 7.4 percent and 9.7 percent, this estimate translates to direct effects on wage inflation of 1.3 and 1.1 percentage points during the two phases.

The final hypothesis test regarding the effectiveness of the Carter controls program is a test for the Carter Administration's success in preventing the energy price explosion of 1979-80 from getting built into wage demands. In particular, we test the hypothesis that the workers did not take into account price increases directly attributable to the energy-price explosion in formulating their wage demands.

Our approach is to estimate the coefficient of

#### EXPLOSION

$$= \sum_{i=1}^{12} \lambda_i (ENERGY - \dot{P})_{-i} \delta_{-i},$$

where  $\lambda_i, i=1, \dots, 12$ , are the estimated coefficients of the distributed lag on prices,  $L(\dot{P})$ ;  $(ENERGY - \dot{P})_{-i}$  is the difference between the increases in energy prices and the *CPI*, lagged  $i$  quarters; and  $\delta$  is a dummy variable equal to 1 from 1979:I to 1980:II

and zero otherwise.<sup>10</sup> If the energy price increases of 1979-80 were treated exactly as other price increases, the coefficient of *EXPLOSION* would be zero; if these increases in excess of the rise of other components of the *CPI* were entirely swallowed by workers, the coefficient would be equal to  $\omega/(1-\omega)$ , where  $\omega$  is the relative importance of energy prices in the *CPI* ( $\omega/(1-\omega) = .115$  in 1979-80).<sup>11</sup>

To test the hypothesis that the Carter program prevented a full pass-through of the energy price explosion, we must confirm that workers typically treat energy price increases just as they treat any other price increase in the formulation of wage demands. We do this by the inclusion in equation (1.7) of a distributed lag on the difference between changes in energy prices and the overall inflation rate, denoted  $L(ENERGY - \dot{P})$ . If workers typically treat energy price increases no differently than increases in other components of the *CPI*, the coefficient of this difference would be zero. As can be seen from Table 1, the estimated coefficient is statistically insignificant.

The coefficient on *EXPLOSION* is remarkably large and statistically significant. The coefficient is more than  $1\frac{1}{2}$  times  $\omega(1-\omega)$ , which is consistent with the hypothesis that much of the indirect effect of the energy price explosion, as well as the direct effect, was not passed through in the form of higher wage demands. Equation (1.7) has the lowest standard error in Table 1. It is also superior to the other equations in two other im-

portant respects of equation (1.6) with respect to the parameters, evaluated at their estimated values. The estimated coefficients of this artificial regression were identically equal to zero (up to rounding error), indicating that the iterative process converged to a maximum of the likelihood function. The variance-covariance matrix of this artificial regression provides a consistent estimate of the variance-covariance matrix of the original regression, equation (1.6), and is used to calculate the  $t$ -statistics reported in Table 1. The Davidson-MacKinnon correction made little difference in equation (1.6); most of the  $t$ -statistics were virtually unaffected, the only perceptible changes being small (absolute) increases in the  $t$ -statistics for *STANDARDS1·R* (from -2.43 to -2.56) and *STANDARDS2·R* (from -1.68 to -1.74). In other wage equations discussed below, however, the correction resulted in substantial changes in many estimates—especially the standard errors of particular interest.

<sup>10</sup>Percentage increases in the energy component of the *CPI* during 1978, 1979, and 1980 were as follows:

	I	II	III	IV
1978	3.6	9.7	10.9	5.8
1979	16.8	52.5	62.4	19.9
1980	46.6	26.5	8.1	-2.4

<sup>11</sup>Estimation of the coefficient of *EXPLOSION* required an iteration between it and the coefficients of  $L(\dot{P})$ . The approach taken was identical to that used in estimating equation (1.6). The Davidson-MacKinnon correction lowered the  $t$ -statistic on  $L(\dot{P})$  from 25.69 to 13.42 and that on *EXPLOSION* from -4.35 to -2.76.

<sup>b</sup>See Table 1.

portant respects. First, the coefficient of trend productivity growth  $R$  is closer to 1.0 and, in fact, is (barely) statistically insignificantly different from 1.0. Second, the sum of the coefficients on lagged prices (0.9) is higher (though still statistically significantly less than 1.0).

### B. Wage-Equation Sensitivity Analysis

Because wage equations are notoriously nonrobust, we have estimated several alternative wage equations to test for sensitivity of the strong result in equation (1.7) to changes in its specification.

For easy comparison, equation (1.7) is reproduced in Table 2.<sup>12</sup> The first sensitivity test, shown in equation (2.8), indicates that a constant term added to the basic equation (1.7) is statistically significant. Moreover, addition of the constant term makes the coefficient of the trend-productivity variable,  $R$ , statistically insignificant. Equation (2.8), however, is much less plausible, primarily be-

<sup>12</sup>The *t*-statistics in Table 2 are all calculated using the artificial-regression method described above. In every case, the Davidson-MacKinnon correction cut the *t*-statistic on *EXPLOSION* roughly in half.

cause of the resurrection of substantial money illusion, as indicated by the decline in the sum of the coefficients on lagged prices from .9 to .5. In addition, the *t*-statistic on the sum of the price coefficients falls from 13.4 to 3.5. Theory tells us that the constant term does not belong in this equation.

Equation (2.9) tests for the possible effect of cyclical, in addition to trend, productivity movements on rates of wage increase by introducing the difference between actual and trend productivity as an explanatory variable (*PRODDEV*). The coefficient is insignificantly different from zero, indicating that wage growth is not affected by cyclical productivity changes.

Potentially the most troubling sensitivity test that we carried out was the replacement of the *CPI* by the Fixed Weighted Personal Consumption Expenditure (*PCE*) Price Index from the National Income Accounts. The resultant regression, which must be run on a shorter sample period, is reported as equation (2.10) in Table 2. The substitution substantially lowers the point estimate and eliminates the statistical significance of the effect of the Carter program in preventing the energy price explosion from getting built into the wage-price process.

Equation (2.11) is the basic equation (1.7) run on the shorter sample period of equation (2.10). The large and statistically significant estimate of the effect of the Carter program in equation (2.11) indicates that the diminution in the estimated effect in equation (2.10) is attributable to the substitution of the *PCE* Price Index for the *CPI*, rather than the shortening of the sample period.

There is little to choose—either in goodness of fit or plausibility of the coefficient estimates—between equations (2.10) and (2.11).<sup>13</sup> The issue, then, is which price index is appropriate to use in a wage equation—that is, which price index is used by workers in formulating their estimate (or expectation) of changes in the cost of living. It seems

apparent that workers typically use the *CPI* rather than the *PCE* Price Index: the *CPI* is almost always used in formal cost-of-living adjustment clauses, and it is by far the most visible measure of the cost of living. As the principal difference between the two indexes is the treatment of home ownership (the *CPI* until 1983 used home-ownership costs, whereas the *PCE* Price Index uses imputed rent), a test of the hypothesis that workers base wage demands on the *PCE* Price Index rather than the *CPI* is approximately equivalent to a test of a differential response to changes in home-purchase prices and mortgage-interest costs in the *CPI* as compared to changes in other components of *CPI*.

Equation (2.12) tests this hypothesis by including as an explanatory variable a distributed lag on the difference between home-purchase and mortgage-interest costs and the total *CPI*,  $L(\text{HOMEOWN} - \dot{P})$ . If workers treat these costs differently from other costs (as would be the case if they used the *PCE* Price Index in estimating the cost of living), this coefficient would be different from zero. The estimated coefficient and the *t*-statistic decisively reject the hypothesis that workers treat the homeownership component of the *CPI* differently from other components.

On the basis of this test, but more fundamentally on the basis of common sense, we believe that the *CPI* is the appropriate measure of the cost of living to be used in a wage equation. Nevertheless, the fact that replacement of the *CPI* by the *PCE* Price Index lowers substantially the large estimated effect of the Carter program in equation (1.7) is evidence that the nonrobustness of wage equations makes it quite possible to get conflicting results with reasonable alternative specifications.

### C. Price Equation

Various tests of the effect of the Carter program on the structure of the price equation (not reported here) uniformly and decisively reject the hypothesis of effectiveness. Note, however, that to have an effect on inflation, there is no need for a program to affect the structure of the price equation

<sup>13</sup> Both equations are inferior to the equations run on the larger sample period. Especially noteworthy are the large coefficients of *TRENDPROD* in equations (2.10) and (2.11).

<sup>a</sup>The dependent variable is  $\dot{P}$ ; the sample period is 1954:II–1983:II;  $t$ -statistics are shown in parentheses.

directly. If the structure of the wage equation is changed, a program will lower price inflation indirectly through the pass-through of lower labor-cost inflation in the price equation. Table 3 contains the estimated price equation, to be used in simulations reported below.

The constant term, as expected in the absence of an inflationary bias, is roughly equal to zero.

The percentage change in unit labor costs, evaluated at trend productivity growth, is entered concurrently and with one- and two-period lags. The sum of the coefficients is 0.7, which is about what one would expect in view of the fact that energy prices and home-ownership costs (with relative-importance weights summing to 0.3) are included in the equation as explanatory variables.

The percentage change of energy prices, weighted by its relative importance in the *CPI*, is included both concurrently and with one- and two-period lags (*WTENERGY*). The coefficients sum to 1.0, which suggests that the indirect effects of energy price increases operate through the wage equation.

The variable *WTHOMEOWN* is the (weighted) percentage rate of change of home-purchase and mortgage-interest costs in the *CPI*. It is included not because it is exogenous (for certainly it is not), but rather to correct for inappropriate treatment of the costs of home ownership in the calculation of the *CPI* before January 1983. Most index-number specialists agree that before 1983 the

*CPI* was overly sensitive to changes in mortgage interest rates and home-purchase costs because of conceptual problems with the way that these costs were calculated. The resultant distortion was especially prominent during the last few years before the Bureau of Labor Statistics was forced, by the preponderance of professional opinion, to change its method of calculating home-ownership costs (switching to an imputed-rent approach). Thus, the inclusion of *WTHOMEOWN* can be interpreted as a correction for the earlier mismeasurement of inflation. The coefficient, as expected, is insignificantly different from 1.0.

To test for the possible effect of cyclical productivity changes on inflation, we also include as an explanatory variable the difference between trend and actual productivity growth, *PRODDEV*. The estimated coefficient of this variable implies that 8 percent of the productivity shortfall during a recession is passed through in the form of higher prices. The other 92 percent is absorbed in the fluctuation of profit margins.

The coefficient of the guidepost dummy variable suggests a perverse effect on price inflation. Roughly speaking, the point estimate implies that the labor-cost savings attributable to the guidepost program were not passed through in the form of commensurately lower inflation. The coefficient is not quite statistically significant, however.

The estimated coefficients of the dummy variables, *ESP1* and *ESP2*, indicate that the

Nixon Administration's controls program reduced the rate of price inflation by one percentage point during the tough Phases I and II, but that a price surge during decontrol (Phases III and IV) more than eliminated the earlier salutary effects. The sum of the coefficients of *ESP1* and *ESP2* is positive and statistically significant, implying a perverse effect of the entire program.<sup>14</sup>

Blinder and Newton also found that a postcontrols catch-up eliminated the large initial effects of the Nixon program. Our results, however, indicate that the catch-up came during the decontrol period, rather than after the controls were formally lifted in 1975. This timing contrast is probably attributable to different treatments of energy prices. The postcontrols catch-up is somewhat confounded with the effects of the 1973-74 oil-price explosion. Energy prices took off in the last part of 1973 and surged through the first two quarters of 1974; controls were lifted early in the second quarter of 1974. The dependent variable of Blinder and Newton is the underlying rate of inflation, which excludes energy prices. As a surge in energy prices gets built into the underlying rate with a short lag, we feel that the 1974 price increases attributed by Blinder and Newton to a postcontrols catch-up might in fact be caused by the lagged effect of the energy price explosion.<sup>15</sup>

#### D. Simulations

The direct effect of the Carter program on wage inflation (assuming that the absorption of the energy price increases was attributable to the program rather than to other structural change) can be obtained by simulating the wage equation (1.7). The full effect of the program, taking into account the interaction between prices and wages, is estimated by simulating the wage equation (1.7) and the price equation jointly.

These simulations are depicted in Figures 1-3 and summarized in Table 4. The Pro-

<sup>14</sup> The estimated covariance between the coefficients of *ESP1* and *ESP2* is .003.

<sup>15</sup> A postcontrols dummy is statistically insignificant in our equation.

Controls and Postcontrols (1978:IV– 1983:II)	8.16	9.37	–1.21	8.09	10.02	–1.93	9.17	10.44	–1.27

<sup>a</sup>Average annual percentage rates of change.

gram On calculations are predicted percentage changes using equation (1.7) (and, except in Figure 1, the price equation) as estimated; the Program Off calculations are obtained by setting the *EXPLOSION* variable equal to zero in all quarters. The difference between the two percentage changes is the simulated effect of the program. In each case, there is no effect until 1979:II because energy prices did not take off until 1979:I (i.e., the *EXPLOSION* variable is equal to zero before 1979:I) and prices first enter the wage equation with a one-period lag.

The simulated direct effect on wage inflation, illustrated in Figure 1, quickly climbs to two percentage points by the end of 1979 and persists at that level through most of 1980. Through 1981 and 1982, the simulated effect declines slowly but monotonically, virtually vanishing by early 1983. The average direct effect on wages over the course of the Carter program (1978:IV–1980:IV) is 1.3 percentage points. This estimate is roughly consistent with the alternative estimates of the direct effect of the program on wages reflected in equations (1.1)–(1.6) in Table 1.

The more provocative aspect of this simulation is the persistence of the effect until long after the program was formally abandoned in January 1981. This enduring effect is technically attributable to the twelve-quarter lag on prices,<sup>16</sup> and the maintained

hypothesis that workers were persuaded to absorb the energy price increases for all time—that is, no attempt was made to recoup these concessions after the program was abandoned. (An alternative equation that constrains the effect of the program to end in 1980:IV has a significantly worse fit than equation (1.7); various equations incorporating postcontrols catch-up variables instead of a persistent absorption of the energy price increase are also inferior to equation (1.7).)

The joint simulation of the wage equation (1.7) and the price equation indicate that, as would be expected, taking full account of the interaction between wages and prices substantially enhances the simulated effect on wage inflation (Figure 2). Over the period of the Carter program, the simulated effect is increased by only 0.2 percentage points (from 1.3 to 1.5 percentage points), but the big difference is the large simulated effects after

significant all the way to the end of the 12-quarter lag:

Lag	Coefficient	t-Statistic
–1	.16	4.3

<sup>16</sup>The mean lag is 4.4 quarters and, although the weights are largest for short lags, coefficients remain

the program was abolished. In fact, the full effect on wages persists at 2 percentage points until mid-1982, and as recently as 1983:II the effect was still  $1\frac{1}{2}$  percentage points.

The simulated effect on price inflation (Figure 3) during the Carter program is 0.9 percentage points, but from early 1980 until early 1983, the simulated effect on the rate of change of the *CPI* is substantially greater than 1 percentage point, sometimes approaching 2 percentage points. (The effect on price inflation is not as large as the effect on wage inflation because the sum of the coefficients on unit labor costs in the price equation is less than 1.0.)

### III. Concluding Remarks

The foregoing tests, like most econometric tests, are unlikely to change the opinions of those with strong priors about the effectiveness of controls. They nevertheless make it clear that, for one reason or another, the energy price surge of 1979–80 was not passed through in the usual manner. As a result, from late 1978 until the middle of 1983, wage inflation was about 2 percentage points lower and price inflation was about 1 percentage point lower than would have been expected on the basis of the structure of our wage-price model.

The foregoing simulations and hypothesis tests maintain that the only change in the structure of the wage-price process in recent years was caused by the Carter Administration Pay and Price Standards Program. It is, of course, possible (some might say likely) that there are other causes of the change in structure. For example, casual inspection indicates that there may have been a worldwide moderation of wage demands in the face of the acceleration of inflation brought about by the 1979–80 energy crisis. Since most countries did not introduce incomes policies during this period, it is possible that a more fundamental structural change took place worldwide and that this accounts for the large estimated effect of the Carter program. On the other hand, a common response to an international shock could reflect the interdependence of Western economies and the transmission of a programmatic effect in the United States alone. A systematic

international comparison would be required to sort out these phenomena.

Alternatively, it is possible that the wage equation is misspecified, in the sense that the effect of price changes on wage demands is nonlinear—in particular, that wage demands increase less than proportionately as inflation grows. There are institutional reasons for this phenomenon—for example, caps on costs-of-living adjustments. It may well be that the reason wages behaved moderately in 1979–80 in the face of rampant inflation brought on by the worldwide energy crisis has nothing to do with the Carter program and is instead attributable to the fact that this inflation was outside the bounds of the postwar U.S. experience and that linear models estimated on the basis of that experience would automatically overpredict wage increases during a period of double-digit inflation. Additional research is required to answer these questions.

### APPENDIX

#### *Variable Definitions and Data Sources*<sup>17</sup>

$\dot{W}$  = percentage change in *PAY*.

$PAY = J \times WSS/WS$ .

*J* = hourly earnings index of production workers in private nonfarm sector. This series is adjusted for overtime (in manufacturing) and for interindustry shifts in employment. 1954–63: Gordon (1971); 1964–83: Bureau of Labor Statistics (BLS).

*WSS* = compensation of employees. National Income Accounts (NIA).

*WS* = wages and salaries. NIA.

$\dot{P}$  = percentage change in the *CPI* for urban consumers (all items). BLS.

*CHPCE* = percentage change in the Fixed Weighted Personal Consumption Expenditures Price Index (all items). Bureau of Economic Analysis.

$U - \bar{U}$  = unemployment rate for civilian workers less the natural unemployment rate calculated by Gordon (1978). BLS.

<sup>17</sup> Unless otherwise noted, all variables are seasonally adjusted. All percentage changes are at annual rates.

$CHSSTAX$  = percentage change in  $1/(1-TWER/WS)$ .

$TWER$  = employer contributions for social insurance. NIA.

$CHMIWAGE$  = percentage change in the minimum hourly wage for all covered and nonexempt workers (not seasonally adjusted). Office of Fair Labor Statistics, Department of Labor.

$GUIDEPOSTS$  = .25 for 1962:I, .5 for 1962:II, .75 for 1962:III, 1 for 1962:IV to 1966:IV, .75 for 1967:I, .5 for 1967:II, .25 for 1967:III, 0 otherwise.

$ESPI$  = .5 for 1971:III, 1 for 1971:IV to 1972:IV, .167 for 1973:I, 0 otherwise.

$ESP2$  = .833 for 1973:I, 1 for 1973:II to 1974:I, .333 for 1974:II, 0 otherwise.

$STANDARDS1$  = .667 for 1978:IV, 1 for 1979:I to 1979:IV, 0 otherwise.

$STANDARDS2$  = 1 for 1980:I to 1980:III, .667 for 1980:IV, 0 otherwise.

$STANDARDS = STANDARDS1 + STANDARDS2$ .

$R$  = estimated trend rate of productivity growth, obtained by regressing  $CHPROD$  on  $CHGAP$ ,  $CHGAP_{-1}$ ,  $TIME$ , and  $DEOE$ , the period of estimation being 1953:I to 1980:III, and using the fitted values setting  $CHGAP$ ,  $CHGAP_{-1}$ , and  $DEOE$  equal to zero.

$CHPROD$  = percentage change in output per man-hour in the nonfarm business section. BLS.

$GNPGAP = ((POTGNP - GNP) / POTGNP) \times 100$ .

$GNP$  = Gross National Product-1972 dollars. NIA.

$POTGNP$  = Potential  $GNP$ -1972 dollars. Council of Economic Advisors.

$CHGAP$  = percentage change in  $GNPGAP$ .

$TIME$  = 1 for 1953:I, 2 for 1953:II, and so on.

$DEOE$  = end-of-expansion dummy constructed by Gordon (1979).

$ENERGY$  = percentage change in the energy component of the  $CPI$  (not seasonally adjusted). Constructed using BLS data.

$WTENERGY = ENERGY$  multiplied by relative importance of energy component of the  $CPI$ .

$WTHOMEOWN$  = weighted percentage change in the home-purchase and mortgage-interest cost component of the  $CPI$ , the weight being its relative importance in the  $CPI$  (not seasonally adjusted). Constructed using BLS data.

$PRODDEV = CHPROD$  less  $TREND-PROD$ .

# Stardom and Talent

By MOSHE ADLER\*

The phenomenon of stars is defined by Sherwin Rosen to be one "wherein relatively small numbers of people earn enormous amounts of money and dominate the activities in which they engage" (1981, p. 845). Rosen sets out to explain two aspects of this phenomenon: persons with only a slightly greater talent command much higher incomes than those who are only slightly less talented; output is concentrated on those few who have the most talent. Rosen's explanation consists of two factors: lesser talent is a poor substitute for greater talent, and either the activity can be reproduced endlessly (for example, on records) at a fixed cost, or the cost of production does not rise in proportion to the size of the seller's market (a better surgeon can perform better operations and more of them within a given time).

Rosen explains why large differences in earnings could exist where there are only small differences in talent. This paper explains why large differences in earnings could exist even where there are no differences in talent at all. In other words, it explains why there could be stars among individuals known to have equal talents.

## I. Analysis

The main argument of this paper is that the phenomenon of stars exists where consumption requires knowledge. The consumer's utility function is similar in spirit to

the one developed by George Stigler and Gary Becker (1977), where consumers accumulate "consumption capital." As an example, consider listening to music. Appreciation increases with knowledge. But how does one know about music? By listening to it, *and by discussing it with other persons who know about it*. In this learning process lies the key to the phenomenon of stars.

The learning process in this paper adds to the learning process in the Stigler-Becker framework the element of discussion with knowledgeable individuals. By itself, the Stigler-Becker model is sufficient to yield that consumers will not diversify indefinitely either across activities, or across individuals within a given activity. (Stigler and Becker did not make this point.) An opera fan must forego some fields of interest (say, golf, rock music) for the sake of greater knowledge of opera. Once a field of interest is chosen, the fan must forego having very little knowledge about a great number of performers for the sake of greater acquaintance with the work of a few. Each person ends up with a limited number of artistic activities and, within each activity, a limited number of stars. What remains to be explained is why everyone would choose to have the *same* stars.

Here, the need to discuss with other knowledgeable individuals in order to know is essential. If every individual were knowledgeable about a different artist, no discussion would be possible. One is better off patronizing the same artist as others do. It is plausible to assume that the cost of searching for knowledgeable discussants is minimized if one chooses the most popular artist. Thus, if other artists are not cheaper by more than the savings in search costs, one is better off patronizing the star. Alternatively, if other artists are not sufficiently *better*, one is better off patronizing the star. To reemphasize, the star need not possess greater talent. Stardom is a market device to economize on learning costs in activities where "the more you know

\*Assistant Professor, Department of Economics, University of California, Davis, CA 95616. I thank Alanson Minkler for research assistance and substantial criticism and comments. This paper was motivated by a dispute with Samira Haj.

the more you enjoy." Thus stardom may be independent of the existence of a hierarchy of talent.

## II. The Definition of Talent<sup>1</sup>

Assume an economy with identical consumers and nonidentical producers called artists, denoted by  $X$ ,  $Y$ , and  $Z$ . Let a consumer's utility from the consumption of art,  $U$ , be independent of the consumption of all other goods.

$$(1) \quad U = U(x, y, z),$$

where  $x$ ,  $y$ , and  $z$  are measured in units of time that the consumer devotes to the art produced by  $X$ ,  $Y$ , and  $Z$ . For music this would be listening time and for paintings, observation time.<sup>2</sup>

Two artists,  $X$  and  $Y$ , are said to have lesser, equal, or greater talent if the utility function satisfies the respective condition:

$$(2) \quad U(x, 0, 0) \leq U(0, y, 0)$$

for all  $x$ ,  $y$  such that  $x = y$ . It is not necessary that the inequal will have the same direction at all levels of  $x = y = z$ . It is assumed, however, that this is the case.

## III. The Model

The simplest model assumes only two artists of equal talent,  $X$  and  $Y$ . Learning about the artists involves direct contact with their work (listening to their music, observing their painting, etc.), and discussing the work with other knowledgeable individuals. Assume that the learning process is of a fixed proportion between direct contact time and discussion time. In my model, there is no distinction between learning and consuming. One enjoys both direct contact with art and discussion of art, or one learns through con-

FIGURE 1

sumption. Call the composite good of contact with art and discussion of art—art. The “addictive” nature of art where specialization is preferred yields concave indifference curves. A consumer prefers  $c$  units of  $x$  or  $c$  units of  $y$  to any combination of  $x$  and  $y$  totalling  $c$  units. Figure 1 depicts the indifference map.

To illustrate, the indifference map could be generated by a separable utility function of the form

$$(3) \quad U(x, y) = u(x, 0) + u(0, y).$$

Since  $x$  and  $y$  are of equal talent,  $u$  has only one parameter.

$$(4) \quad u = u(v); \quad v = x, y,$$

if  $x = y$ ,  $u(x) = u(y)$ . Because enjoyment increases with knowledge the marginal utility is increasing:  $u' > 0$ ,  $u'' > 0$ .

To determine the consumer's choice, assume that the only cost in the consumption of art is time. This cost consists of two elements: the actual time devoted to art (direct contact and discussion), and the time devoted to the search for individuals with whom one could discuss the artist one chooses. Assume that the search time is  $1/X$  and  $1/Y$  where capital letters indicate the total number of consumers who choose the

<sup>1</sup>Thanks go to Leon Wegge for insisting that such a definition is required, and to Tom Russell for simplifying my definition.

<sup>2</sup>The time devoted to art includes the time devoted to the discussion of art. See below.

FIGURE 2

corresponding artist. Assume also that this search cost has to be incurred for each unit of art consumed. The consumer devotes  $I$  units of time over his or her life to art and the search involved. The budget constraint of our consumer is

$$(5) \quad x(1 + 1/X) + y(1 + 1/Y) = I.$$

From the budget constraint and the indifference curves it is clear that the consumer will specialize: he or she will either consume  $x$  or  $y$ , not both. If  $X = Y$  the consumer will be indifferent between the two, but if more consumers consume  $x$ ,  $X > Y$ , our consumer will be better off consuming  $x$ . Figure 2 depicts the maximization problem. In this discussion, the existence of a super star among equals is apparent.<sup>3</sup>

Note that whereas all individuals could have equal talents, not all individuals would be artists. An artist for the purpose of this paper is one who produces a good with the

quality of increasing marginal utility in consumption. Only artists could be stars.

#### A. More than One Star

In the world of art, there is more than one star. A minor modification in the model would result in multiple stars. Assume that at low levels of consumption consumers prefer to specialize, but that at high levels diversification becomes preferable. In other words, the indifference curves are concave at low levels of utility and convex at high levels of utility. Figure 3 depicts the indifference map. A consumer who devotes little time to art would patronize only one artist. A consumer who devotes more time, would patronize both artists. This result can be generalized: the more time one devotes to art, the larger would be his or her set of stars.

#### B. Pricing

So far I have assumed that the only cost to the consumer in the consumption of art is time. However, stardom produces savings in time costs and the star could absorb part of these savings.

Assume that the cost of production of art is zero. If there are pecuniary costs to the consumption of art, the budget constraint becomes

$$(6) \quad x(P_x + w + w/X) + y(P_y + w + w/Y) = Iw,$$

where  $P_x$  and  $P_y$  are the rental prices per unit of time of  $X$  and  $Y$ , respectively, and  $w$  is the wage rate. The consumer will choose  $X$  over  $Y$  as long as  $P_x - P_y < w/Y - w/X$ .<sup>4</sup>

#### C. Amateurs Who Excel

My model allows the star to remain a star even though an amateur could have a greater talent. To see this point, denote by  $U_1$  the utility from the consumption of  $X$ ,  $U_2$  the

<sup>3</sup>This paper has much in common with the literature on the bandwagon effect. It adds, however, to this literature by explaining the effect in one set of goods. Moreover, this set of goods is probably more prone to the bandwagon effect than other goods. One could imagine, for instance, a system without fashion in clothing. This would be the case where uniforms were required. Since, however, the source of the bandwagon effect in this paper is knowledge, the phenomenon of superstardom would be much more difficult to uproot in the goods discussed here.

<sup>4</sup>The  $X$  markup could be even larger, since the utility from an artist that consumers already know is greater. See the discussion of Figure 4 below.

## D. Different Tastes

FIGURE 3

FIGURE 4

utility from the consumption of  $Y$ . If  $Y$  is more talented, then for  $x = y$ ,  $U_1(x) < U_2(y)$ . The quantities of  $x$  and  $y$  that the consumers could consume given his budget,  $I$ , are  $I/(P_X + w(1 + 1/X))$  and  $I/(P_Y + w(1 + 1/Y))$ , respectively. The consumer will continue to pick  $x$  as long as

$$(7) \quad U_1\left(I/P_X + w\left(1 + \frac{1}{X}\right)\right) > U_2\left(I/P_Y + w\left(1 + \frac{1}{Y}\right)\right).$$

Figure 4 depicts this condition.

Thus far I have assumed identical consumers and an identical unspecified artistic activity which they all consume. If consumers have different tastes, there would be different artistic activities (singing, painting, pottery) and within each activity different types of that activity (opera vs. rock music, abstract vs. realistic paintings). Consumers of each category have similar tastes, but this need not be the case across categories. Each category constitutes a market with its own stars. Of course, if there isn't any group of consumers with similar tastes there might not be any stars. But this is equally valid in the model developed here and in many other models, including Rosen's.

## E. Who Would Be the Star?

If everybody could be, who would be the star? My answer would be: luck would determine. (By luck, I mean factors other than talent.) But before I elaborate, a word on the relevance of the question to this paper.

According to this paper, stardom and money have similar characteristics. First, bills of all colors could serve as money and likewise all artists could be stars. Second, efficiency calls for only one money and likewise efficiency calls for very few artists with public recognition. Both characteristics exist in the case of money regardless of the process that determines which good would be the medium of exchange. I assert that the same independence exists here: the characteristics of stardom do not depend on the process by which a star evolves. Bearing this qualification in mind, the literature on the development of the medium of exchange, especially Robert Jones (1976), suggests a tentative outline of an answer, and is applied presently with some modifications.

Assume that at first consumers believe that all artists are equally likely to become stars, and that each consumer picks one artist at random. Assume that consumers live  $n$  periods and revise their prior distributions after each period. If there were a slight majority of consumers that picked  $X$  as their choice,  $X$  would snowball into the star because after each period this majority would increase. In

FIGURE 5

other words, if at any period of time an artist had a market share only slightly larger than everybody else, this share would increase steadily. Nonetheless, the lucky artist need not capture the whole market even if a time would come when everybody would recognize him or her as the star. A consumer who did not find whom the star was for a long time might be better off continuing with an erroneous choice than switching. He or she would be only beginning to learn about the star, whereas his or her knowledge about the other artist (who is equally talented) is already extensive. This advantage in knowledge about the nonstar has to be weighed against lower search costs for discussants if one were to switch to the star.

Figure 5 depicts a consumer who thought that  $X$  was the star, but in period  $i$  finds out that he was wrong.  $V$  is the "indirect" utility function, or the utility the consumer derived at period  $i$ ,  $i < n$  from consuming  $I/(1+1/X)$  units of  $X$  where  $I$  is the amount of time the consumer devotes at each period to both art and search cost. (As was shown, the consumer will choose either  $x$  or  $y$ , not both.) Since knowledge increases utility, previous consumption is an argument of

the utility function:  $V = V(I/(1+1/X), \bar{x})$ , where  $\bar{x}$  is the prior consumption of art. The terms  $\bar{x}$  and  $X$  could be replaced by  $\bar{y}$  and  $Y$ .

At period  $i$ , when the consumer discovers who the true star is, his indirect utility would be higher if he consumed the "false star" (the  $xx$  curve in Figure 5). However, since his search costs for discussants would be lower with the true star,  $V$  would grow faster if he switched (the  $yy$  curve). Only if area  $B$  is greater than  $A$  in Figure 5, will it pay to switch.

#### IV. Conclusion

This paper explains why a hierarchy in income could exist without a hierarchy in talent. In other words, it explains why there could be stars among individuals known to have equal talents. The main argument was that the phenomenon of stardom exists where consumption requires knowledge. The acquisition of knowledge by a consumer involves discussion with other consumers, and a discussion is easier if all participants share common prior knowledge. If there are stars, that is, artists that everybody is familiar with, a consumer would be better off patronizing these stars even if their art is not superior to that of others.

# Advertising and Economic Welfare

By LEN M. NICHOLS\*

Is advertising socially excessive? Economists have been reluctant to consider this question, for there appeared to be no rigorous method of analyzing cases in which advertising influences tastes. Some recent studies have made fundamental contributions to this debate (Avinash Dixit and Victor Norman, 1978; Yehuda Kotowitz and Frank Mathewson, 1979), but no consensus has emerged.

Dixit and Norman were the first to establish a rigorous methodology. They evaluated social welfare ( $SW$  = consumer's surplus + profits) under pre- and post-advertising market equilibria, using pre-advertising tastes for one ranking and post-advertising tastes for another ranking. When the  $SW$  rankings were identical, Dixit and Norman claimed that unambiguous inferences could be drawn. In general, they concluded that the profit-maximizing level of advertising will be excessive under a variety of product market structures.

Franklin Fisher and John McGowan (1979) criticized Dixit and Norman for including advertising in the utility function but ignoring the direct effect that advertising has on utility in their welfare analysis. Dixit and Norman (1979) countered that advertising merely shifts the preference ordering over goods, and that it is this preference yardstick that matters.

Welfare conclusions about advertising can be generated less controversially within the framework suggested by George Stigler and Gary Becker (1977). They treat utility as if it were generated by "commodities" which individuals produce with purchased

goods, time, human capital, and firms' advertising. Their commodities can be interpreted similarly to what Kevin Lancaster (1966) calls a "characteristic," the terminology used herein.<sup>1</sup>

As an example, consider tennis. We buy racquets and balls, not to own them per se, but rather to enjoy playing the game. Playing the game actually generates utility, and this characteristic is produced by an individual's racquet, balls, human capital (skill level), and time.

Thus preferences are ordered over characteristics, not over goods. Advertising can lower the shadow price of a characteristic by increasing the ability of the purchased good to produce the desired characteristic. This is accomplished by providing the consumer with different information or beliefs about the product than previously held.

Suppose a perennial tennis champion states a preference for a particular brand of racquet. This enhances the self-image of amateur owners of that brand and increases their enjoyment of the game without changing their expenditures. The per unit cost of the characteristic will decline, making current owners of the racquet likely repeat customers and current shoppers more likely to choose the star's preferred brand. Observe that advertising has increased the demand for a market good that produces the now cheaper char-

\*Assistant Professor of Economics, Wellesley College, Wellesley, MA 02181. I am indebted to Ralph Bradburd, David Lindauer, Ken Koford, Robert Feinberg, Ann Witte, and two anonymous referees for helpful comments and suggestions on earlier drafts. Any remaining errors and ambiguities are my sole responsibility.

<sup>1</sup>Lancaster developed an approach to consumer theory wherein market goods are desirable only because they provide utility-generating characteristics. In general, each market good provides many such characteristics, thus each input into the consumer's process of generating utility has many outputs. Stigler and Becker have in mind a world wherein each output, a single utility-generating commodity, is produced by multiple inputs; for example, purchased goods, human capital, time, and beliefs. A fully general model would obviously have multiple inputs and outputs. In that sense the approach employed herein is a special case, but one that is particularly well suited for the welfare analysis of advertising.

acteristic. The Stigler-Becker framework enables us to interpret an apparent *shift* in the product demand curve as a movement *along* a characteristic demand curve induced by increased advertising's reduction in the shadow price of the characteristic. Thus we can measure consumer's surplus as the area under the stable characteristic demand curve above the shadow price, and conduct welfare analysis of market equilibria under various levels of advertising without concern for which product demand curve is appropriate.

Kotowitz and Mathewson implicitly use the Stigler-Becker framework when they assume utility depends on two-dimensional quality. Advertising affects one of the dimensions, and the costlessly observable characteristics of the good affect the other. Thus utility is produced by the verifiable good and beliefs about that good, which are in turn affected by advertising. Their welfare conclusions about the social optimality of advertising are ambiguous, but they do isolate the factors that determine this result.

This paper generates welfare conclusions about advertising within the Stigler-Becker framework. A major result is that the social optimality of the profit-maximizing level of advertising depends upon the market structure of the produced characteristic and not upon the market structure of the purchased good. In addition, the method of analysis casts light upon the important insight of Dixit and Norman. Finally, the analysis produces a testable hypothesis on advertising's optimality for any firm or industry.

### I. Assumptions and the Model

Since profits are assumed to be maximized by firms' advertising choices, the effect of advertising on social welfare may be inferred by differentiating consumer's surplus with respect to advertising and evaluating this derivative at the profit-maximizing level of advertising.<sup>2</sup> This procedure is equivalent to

<sup>2</sup> This may be done unambiguously only when advertising by one firm does not affect the profits of another firm, i.e., there is no public good nor rival message cancellation effect of any firms' advertising. Future work will extend the analysis to these cases.

asking the question, could consumers be made better off with a different level of advertising than profit-maximizing firms will choose to provide?

This can be answered directly with the following model. Utility of the typical consumer is derived from the produced characteristics  $Z$  and  $Y$ . Following Stigler and Becker's simplification,  $Z$  is the product of a function of advertising and the quantity of a marketed good  $X$ ;  $Z = g(A)X$ . The function  $g(A)$ , the marginal characteristic productivity of  $X$ ,  $\partial Z / \partial X$ , summarizes the consumer's attitudes about the effectiveness of advertising. Ultimately, the consumer decides if a good is search or experience, and if an advertisement is informative or persuasive.<sup>3</sup> The  $Y$  is the composite nonadvertised good. Thus  $U = (g(A)X, Y)$ .<sup>4</sup>

Utility maximization subject to the budget constraint yields the following necessary conditions ( $U_z = \partial U / \partial Z$ ,  $U_y = \partial U / \partial Y$ ):

- (1)  $U_z / \lambda = P_x / g(A)$
- (2)  $U_y / \lambda = P_y$
- (3)  $I = P_x X + P_y Y$ ,

where  $\lambda$  is the Lagrangian multiplier, the marginal utility of income. Expression (1) shows that the shadow price of the characteristic  $Z$  is  $P_z = P_x / g(A)$ . This seems similar to Philip Nelson's (1974) notion of price per unit of utility.

Denoting the solutions to (1), (2), and (3) as  $X^*$ ,  $Y^*$ , and  $\lambda^*$ , we know that utility is maximized for a given level of advertising

<sup>3</sup> Past advertising that is now perceived to have been misleading will lower the characteristic productivity of currently produced (or remaining stocks of)  $X$ . Profit-maximizing firms will consider this future credibility cost when formulating their advertising messages. Kotowitz and Mathewson show that misleading advertising may be profit maximizing for a while given certain quality production cost and initial consumer perception parameters. If this is the case, expected characteristic flow will adjust and purchase decisions will be changed accordingly. This adjustment process is implicitly assumed to be performed each period.

<sup>4</sup> For all of the results to hold, we must make the conventional assumption that  $U(Z, Y)$  is strictly quasi concave.

when

$$(4) \quad U = U(g(A)X^*, Y^*).$$

This implies that income must be allocated according to

$$(5) \quad I = P_x X^* + P_y Y^*.$$

Differentiating (5) with respect to advertising yields a result that will be useful later in the welfare analysis,

$$(6) \quad -X^*(\partial P_x / \partial A) = P_x(\partial X^* / \partial A) + P_y(\partial Y^* / \partial A).$$

Now, to consider the question of consumer welfare and advertising, we differentiate (4):

$$dU/dA = U_x[X^*g'(A) + g(A)(\partial X^* / \partial A)] + U_y(\partial Y^* / \partial A).$$

Substituting from the first-order conditions, we have

$$dU/dA = \lambda \left[ (P_x X^* g'(A) / g(A)) + P_x(\partial X^* / \partial A) + P_y(\partial Y^* / \partial A) \right],$$

and using (6),

$$(dU/dA)/\lambda = [P_x X^* / A] \left[ (g'(A)A) / g(A) - (\partial P_x / \partial A)(A/P_x) \right].$$

Since  $(g'(A)A)/g(A)$  is the advertising elasticity of the characteristic productivity of  $X$ ,  $(E_{g,A})$ , and  $(\partial P_x / \partial A)(A/P_x)$  is the advertising elasticity of the price of  $X$ ,  $(E_{P_x,A})$ , we interpret

$$(7) \quad (dU/dA)/\lambda = (P_x X^* / A) [E_{g,A} - E_{P_x,A}].$$

Since  $\lambda$  is the marginal utility of income, the left-hand side of (7) may be interpreted as the consumer's willingness to pay for more advertising at the margin, the shadow price of advertising. If this willingness to pay is

positive (negative, zero) at the profit-maximizing level of advertising ( $\partial \pi / \partial A = 0$ ,  $A = A^*$ ), it may be concluded that advertising is under- (over-, optimally) supplied by the free market. Advertising is undersupplied if, at the profit-maximizing margin, increased advertising raises the characteristic productivity of the purchased good  $X$  more (in percentage terms) than it increases the market price of  $X$ . Advertising is oversupplied when the market price of  $X$  is increased proportionately more than the characteristic productivity is enhanced. Finally, equation (7) suggests that advertising is optimally supplied when advertising raises the market price and the characteristic productivity in equal proportions.

To focus the welfare analysis on the unchanging characteristic demand curve in  $P_z, Z$  space, note that  $P_z = P_x / g(A)$ ,  $\Rightarrow E_{P_z,A} = (\partial P_z / \partial A)(A/P_z) = E_{P_x,A} - E_{g,A}$ . Thus equation (7) could be written as

$$(8) \quad (dU/dA)/\lambda = (P_x X^* / A) [-E_{P_z,A}].$$

We can then say that advertising is undersupplied at the margin when it decreases  $P_z$ —the last unit of advertising allows the consumer to slide down the characteristic demand curve so that  $Z$  consumption and utility rise. If advertising raises  $P_z$ ,  $Z$  consumption and utility fall with the last unit of advertising, and advertising has been oversupplied. If advertising does not affect  $P_z$ ,  $E_{P_z,A} = 0$  and advertising is optimally supplied. In this case, the consumer has obtained the lowest possible  $P_z$ . The inability of advertising on  $X$  to affect the price of  $Z$  is how Stigler and Becker define a perfectly competitive characteristic market. Thus perfect competition in  $Z$  is a sufficient condition for the social optimality of advertising on  $X$ . The following analysis makes clear that the market structure of the purchased good  $X$  does not affect the social optimality of advertising on  $X$ .

## II. The Roles of the Firm and each Market's Structure

As in Stigler and Becker's analysis, the  $X$  producing firm is assumed to maximize profits by choosing output and advertising. In

general, profit maximization requires the marginal revenue of both output and advertising to equal their respective marginal costs. Despite the presence of advertising, the traditional pricing rules continue to hold.<sup>5</sup> When the market for  $X$  is perfectly competitive,  $P_x = MC_x$ , and when  $X$  is imperfectly competitive,  $P_x = MC_x / (1 - (1/E_{x,P_x}))$ .

The market for  $Z$  is more complicated, because consumers must produce  $Z$  with purchased goods and their own attitudes. In general, the same quantity of  $Z$  can be produced by a variety of  $X_i$  and  $g(A_i)$  combinations, where  $i$  could range over competing brands as well as functionally different products. A perfectly competitive  $Z$  market has an infinite variety of  $X_i$  and  $g(A_i)$  combinations that can produce the same  $Z$ , thus the equilibrium price of  $Z$  is exogenous to the individual firm producing and advertising  $X_i$ . No individual producer of an  $X_i$  can affect this  $P_z$  by advertising more or less, or by changing its product price, for a change in the price of  $Z$  indirectly produced by one firm will cause all consumers to shift to the lowest-cost  $Z$  technology. An imperfectly competitive  $Z$  market is one where perfect substitutes do not or are not perceived to exist, and in this case the price of  $Z$  may be altered by the advertising or pricing policies of a given  $X_i$  firm.

Four market structure configurations are possible, all permutations of perfect and imperfect  $X$  and  $Z$ . These four cases can be reduced to two analytically distinct ones: (I) imperfect  $X$  and perfect  $Z$ , and (II) perfect  $X$  and imperfect  $Z$ .<sup>6</sup>

*Case I:* The market for  $Z$  is perfectly competitive, but the market for  $X$  is not.

We know two facts about equilibrium: (a)  $P_x = MC_x / (1 - (1/E_{x,P_x}))$ , and (b) one firm varying the level of advertising on  $X$  cannot affect the perfectly competitive characteristic price, that is,  $(\partial P_z / \partial A) = 0$ .<sup>7</sup> Fact b

guarantees that  $E_{P_z,A} = 0 \Leftrightarrow E_{g,A} - E_{P_x,A} = 0$ , and thus in equations (7) and (8),  $(dU/dA)/\lambda = 0$ . We now have our welfare result that the level of advertising chosen by a profit-maximizing imperfect competitor in  $X$  is socially optimal if that  $X$  is used by consumers to produce a perfectly competitive characteristic. To expand on the example used by Stigler and Becker, in the social prestige characteristic market, ostensibly oligopolistic jewelry designers and furriers who indirectly compete with each other and other indirect producers of social prestige are compelled to advertise the social welfare-maximizing amount if the prestige market is perfectly competitive. The reason this result obtains is the existence of perfect substitutes in use.

*Case II:*  $X$  is perfectly competitive, but  $Z$  is not.

Although it may seem odd at first glance, Stigler and Becker point out that firms producing in perfectly competitive  $X$  markets will find it profitable to advertise if there are alternative technologies for producing  $Z$ , or if there is imperfect information about those technologies.<sup>8</sup> When  $Z$  is imperfectly competitive, advertising for  $X$  can affect the price of  $Z$ . From the consumer's first-order conditions,

$$\begin{aligned} P_z &= P_x / g(A) \Rightarrow P_x = P_z g(A), \\ &\Rightarrow (\partial P_x / \partial A) \\ &= (\partial P_z / \partial A) g(A) + P_z g'(A) \\ &\Rightarrow P_z = (\partial P_x / \partial A) (1/g'(A)) \\ &\quad - (\partial P_z / \partial A) (g(A)/g'(A)) \\ &\Rightarrow P_x = (\partial P_x / \partial A) (g(A)/g'(A)) \\ &\quad - (\partial P_z / \partial A) (\{g(A)\}^2 / g'(A)) = MC_x. \end{aligned}$$

<sup>5</sup>See Stigler and Becker, p. 85.

<sup>6</sup>The results for perfect  $X$  and perfect  $Z$  follow *a fortiori* from Case I. Similarly, the results for imperfect  $X$  and imperfect  $Z$  follow from Case II. All derivations are available from the author on request.

<sup>7</sup>See Stigler and Becker, p. 85.

<sup>8</sup>The implicit assumption in Stigler-Becker and here is that expanding output alone will not affect price, while advertising will. The  $X$  demand curve facing the firm could be infinitely elastic even though advertising can shift it upward within the limits set by the  $g(A)$  function and the profit-maximizing requirement that  $MR_A = MC_A$ .

Using the facts that  $(g(A)/g'(A)) = A/E_{g,A}$  and  $g(A) = P_x/P_z$ , we have

$$(\partial P_x / \partial A)(A/E_{g,A}) - (\partial P_z / \partial A)(P_x g(A)/P_z g'(A)) = MC_x$$

which, when divided by  $P_x$  and rearranged, yields

$$(9) \quad E_{P_x,A}/E_{g,A} = 1 + E_{P_z,A} [g(A)/g'(A)A].$$

Thus, perfection in the  $X$  market does not guarantee socially optimal advertising. Indeed, the result states that the level of advertising that maximizes profits also maximizes social welfare if and only if  $P_z$ , the shadow price of the utility generating characteristic, remains unchanged.<sup>9</sup>

This interpretation suggests a testable proposition on the social optimality of advertising. Since the characteristic  $Z$  is the ultimate object of utility, the demand for  $X$  is a derived demand. When advertising increases the characteristic productivity of  $X$  more than the price of  $X$ , utility maximizers will consume more of  $X$ . Thus if we estimate a sales (physical quantity) equation like

$$(10) \quad Q_s = \alpha + \beta W + \gamma A + \epsilon,$$

where  $W$  is a vector of all other causal influences on sales, a statistically significant  $\hat{\gamma} > 0$  implies that  $E_{P_z,A} < 0$ , and we may infer that advertising is being undersupplied.

Certainly this is more likely when advertising enhances competition, increases the effective price elasticity and thus lowers the market price of a traded good ( $E_{P_x,A} < 0$ ), as in the case of eyeglasses (Lee Benham, 1972). But note that advertising could *increase* the price of the market good and still be undersupplied. This is not possible in the Dixit and Norman formulation, for they assume that preferences are defined over goods, not characteristics. Their assumption that advertising lowers demand elasticity and

raises the price of the argument in the utility function is equivalent to assuming  $\partial P_z / \partial A > 0$ , that is, Dixit and Norman implicitly assume that advertising by a monopolist or oligopolist seller of  $X$  raises the value (characteristic productivity) of  $X$  less than the price of  $X$ . No consumer would choose this and, therefore, advertising is in their view generally oversupplied.

My analysis has identified a special case in which advertising could be oversupplied, specifically when the price of  $X$  is increased proportionately more than the characteristic producing capacity. This could be identified empirically by  $\hat{\gamma} < 0$  in equation (10). Advertising at the profit-maximizing margin reduces total quantity sold.

To illustrate this special case, consider adolescent-sized designer jeans. Marginal advertising messages on these physically similar products raise price more than the jeans' status productivity, but the lack of substitute  $Z$  technologies allow the indirect producers of  $Z$  to extract consumer's surplus. Advertising shifts the product demand curve to the right and makes it less elastic, allowing each firm to raise its price until equilibrium market quantity falls. The decline in equilibrium quantity brought about by advertising here is consistent with Dixit and Norman's analysis in which an increase in output was a necessary condition for  $SW$  to be improved by advertising.

Interestingly, the model suggests that we may interpret  $\hat{\gamma} = 0$  as evidence of optimal advertising. When this is observed, we know that advertising has enhanced the characteristic productivity as much as the market price.

### III. Summary and Conclusions

This paper has used the conceptual insight of Stigler and Becker to develop a framework for determining the social optimality of advertising. Thus it extends recent work by Dixit-Norman and Kotowitz-Mathewson.

One conclusion is that the social welfare-maximizing amount of advertising does not depend upon the market structure of the advertised good. Instead, the market structure of the utility-generating characteristic is crucial. The profit-maximizing level of advertising maximizes social welfare if the char-

<sup>9</sup>Unchanged  $P_z \Rightarrow E_{P_z,A} = 0 \Rightarrow E_{P_x,A} = E_{g,A} \Rightarrow (dU/dA)/\lambda = 0$ .

acteristic productivity of the advertised good is raised as much (proportionately) by advertising at the margin as is the price of the advertised good. This could be inferred when the observed marginal impact of advertising on the quantity of sales is zero. A positive impact of advertising on sales can be taken as evidence of too little advertising—consumers are willing to pay for more. An observed negative impact of advertising on sales suggests that advertising is being oversupplied.

More complicated models should be developed for many remaining issues. I abstracted away from multiproduct firms, where there may be advertising spillover effects across products of a well-known firm. Similarly, the externalities of brand-specific advertising on the characteristic productivities of generic products were ignored. Another interesting complication is that of a single market good being capable of producing multiple characteristics. Finally, it seems that the analysis of advertising in this paper would apply in general to most other forms of product differentiation.<sup>10</sup>

Thus, the model should be interpreted as a polar extreme, not yet ready for definitive policy recommendations. Still, the promise of this characteristic method of analyzing advertising and economic welfare is clear. It

can provide straightforward conclusions in cases where advertising changes preferences over marketed goods, and it can generate clearly testable hypotheses.

# Oligopoly and the Incentive for Horizontal Merger

By MARTIN K. PERRY AND ROBERT H. PORTER\*

Economists have articulated the welfare implications of horizontal mergers.<sup>1</sup> Mergers can reduce industry competition and so result in higher prices for consumers. But, on the other hand, mergers may give rise to efficiency gains (for example, scale economies) that reduce the cost of production or distribution. These welfare discussions of merger often implicitly assume that firms always have an incentive to merge, that is, they can increase profits by raising price and/or reducing cost. This assumption derives from at least two sources. First, at an empirical level, the wave of merger activity at the turn of the century is thought to have been undermined by the Sherman and Clayton Acts, rather than a lack of profitable opportunities. Similarly, the periodic merger waves since then have often been attributed to reduced antitrust enforcement activities. Second, at a theoretical level, industry models such as the symmetric Cournot model exhibit higher prices and profit per firm as the number of firms in the industry is reduced.<sup>2</sup> Thus, there would seem to be profit gains from merger which reduces the number of firms.

However, George Stigler (1950) and others have argued that firms which do not participate in a merger may benefit more than the participants. When a merger occurs, the new firm will typically reduce its production below the combined output of its constituent

firms. As a result, industry price will increase. (This assumes that the cost reductions associated with merger are not too large.) Nonparticipants will then expand output and profit from the higher industry price. Thus, merger participants do not capture all the profits that result from their merger. Because of this externality, mergers which would increase total industry profits need not be privately profitable.

In their 1983 paper, Stephen Salant, Sheldon Switzer, and Robert Reynolds (S-S-R) reexamined the incentive to merge in a static framework. They employed a symmetric Cournot model with linear final demand, and identical constant average costs for each of  $n$  firms. Even though profits per firm are higher with fewer firms, S-S-R demonstrated that the profits of one firm in an  $n$ -firm oligopoly are lower than the profits of two firms in an  $(n+1)$ -firm oligopoly. (This is also true if there are fixed costs that are not large.) From this, they concluded that merger is generally unprofitable in a Cournot oligopoly. The exception to this finding occurs when duopolists merge into monopoly.

However, the S-S-R model severely understates the incentive to merge. The problem is that mergers are not well-defined conceptually. Merger of two firms from a symmetric equilibrium of  $(n+1)$  firms should result in an equilibrium with  $(n-1)$  old firms and one new firm that is "larger" than the others. In particular, the new firm should have access to the combined productive capacity of both merger partners. In the S-S-R model, the merged firm does not differ from the others; it continues to have access to the same technology. Thus, rather than finding that merger is unprofitable, S-S-R find that "lock-up" is unprofitable. The so-called merger increases price to the external benefit of all firms, but the new firm foregoes the production and profits of one of the two original firms. This could be profitable only when an industry monopoly is created from a duopoly. Models

We have benefited from the comments of John Panzar. This work was initiated during 1983 while Porter was a postdoctoral fellow at Bell Laboratories on leave from the University of Minnesota. This article represents our views and assumptions and not necessarily those of Bell Communications Research or the Bell Operating Companies.

<sup>1</sup>Oliver Williamson (1968) documents these effects.

<sup>2</sup>For example, see Perry (1984) and Jesus Seade (1980).

with constant average cost invite this conceptual fallacy by obstructing any notion of assets or firm size.

Raymond Deneckere and Carl Davidson (1983) have shown that the existence of product differentiation can reverse the S-S-R results where the merged firm continues to produce all the products of its constituent firms. We instead propose to deal with the notion of merger directly from the cost side. Unlike S-S-R we can find many circumstances in which an incentive to merge exists, even though the product is homogeneous. Moreover, we can identify the behavioral and structural characteristics that will give rise to such an incentive.

Our formulation of mergers has the following advantages. We explicitly specify a tangible asset that the merged firm acquires from its two partners, which increases the output it can produce at a given average cost. Assets are captured by assuming a capital factor that is in fixed supply for the industry. This structure allows us to address the industry asymmetries caused by the merger of subsets of firms. A merged firm faces a different maximization problem because of its altered cost function and new strategic considerations. Finally, this notion of assets is uniform and fungible enough to discuss any combination of firms in a meaningful and convenient way.

In Section I, we define the cost and demand structure and in Section II, examine a dominant oligopoly model. There is a competitive fringe from which mergers occur to create oligopolists of a particular size. In Section III, we eliminate the fringe and examine a model in which there are large and small oligopolists. Large oligopolists are formed by the merger of two small oligopolists. For both models we characterize the circumstances under which there exists an incentive to merge.

### I. Cost and Demand Structure

The cost structure is the key feature of the model. We assume that there is a factor whose total supply is fixed to the industry, say capital. It is a necessary input in the production process. What will distinguish

firms is the amount of capital which they own. For convenience, we normalize the total quantity of capital to be unity.<sup>3</sup>

The cost function of a firm that owns a fraction  $s$  of the capital stock and produces output  $x$  is denoted  $C(x, s)$ . The output  $x$  is produced with a combination of the fixed factor and a vector of variable inputs  $z$ , according to a smooth concave production function,  $x = F(z, s)$ . Then  $C(x, s)$  is dual to  $F(z, s)$ , where the cost function implicitly subsumes the factor prices corresponding to the input vector  $z$ . We further assume that  $F$  is linearly homogeneous in  $z$  and  $s$ , so that there are constant returns to scale. This implies that the cost function will be linearly homogeneous in  $x$  and  $s$ . Thus, any proportionate increase in output and capital will result in an equiproportionate increase in production costs. Because of the presence of a fixed factor of production, the marginal cost function of any single firm is increasing.<sup>4</sup> Furthermore, since  $C_1(x, s)$  is homogeneous of degree zero, the competitive industry supply curve is fixed at  $C_1(x, 1)$ , irrespective of the distribution of capital among firms. Thus, the competitive industry supply curve is rising, and the marginal cost function of each firm mirrors this industry marginal cost function. In particular, a firm's marginal cost curve is obtained by horizontally shifting the industry marginal cost curve inward, in pro-

<sup>3</sup> Obviously, this suppresses de novo entry into the industry. With entry, the gains to merger diminish in that the magnitude of the price increases would be limited by the supply of new competitors. To capture this effect, it might be preferable to specify a rising supply curve for the fixed factor. We could then examine the impact of entry, which becomes increasingly costly, on the ability of existing firms to raise price through merger and therefore on their reduced incentive to merge. However, this would substantially complicate the model with little gain in insight. The fixed-factor assumption is a limiting case of upward-sloping factor supply. Its convenience derives from fixing the size of the industry so that we can readily examine changes in the number of firms and their sizes.

<sup>4</sup> If  $C(x, s)$  is linearly homogeneous,  $C_i(x, s)$  will be homogeneous of degree zero, where  $C_i(\cdot)$  is the derivative of  $C(\cdot)$  with respect to its  $i$ th argument. Then  $C_{12}(x, s) < 0 < C_{11}(x, s)$ , i.e., marginal costs decrease as capital increases, and so marginal costs must increase with output levels. (Recall, from Euler's Theorem, that  $xC_{11}(x, s) + sC_{12}(x, s) = 0$ .)

portion to the firm's share  $s$  of the industry capital stock. Thus, we can reconstitute the industry structure in any desired pattern without altering the overall size of the industry.<sup>5</sup>

Since the cost function is linearly homogeneous in  $x$  and  $s$ , we specifically rule out scale economies as a motive for merger. Rather, we wish to focus on the incentives to merge that arise solely from firm size and behavior in an imperfectly competitive environment.

In order to illustrate the gains and losses associated with merger, we specify particular cost and demand functions. Both demand and marginal cost are assumed to be linear functions of output. The cost function for a firm with capital stock  $s$  is

$$(1) \quad C(x, s) = s \cdot g + d \cdot x + (e/(2 \cdot s)) \cdot x^2.$$

Clearly,  $C(x, s)$  is linearly homogeneous. Industry fixed costs,  $g$ , are distributed in proportion to holdings of capital. The resulting marginal cost function is linearly increasing with an intercept of  $d$ :

$$(2) \quad C_1(x, s) = d + (e/s) \cdot x.$$

The marginal cost function rotates about the intercept as the amount of capital,  $s$ , increases or decreases.

Similarly, we assume that the industry inverse demand function is linear:

$$(3) \quad P(Z) = a - b \cdot Z,$$

where  $Z$  is industry output. In the next section, we discuss mergers in an oligopoly model with a competitive fringe.

## II. Oligopoly with a Competitive Fringe

In this section, we consider an industry with  $n$  oligopolists, each of which own a fraction  $s$  of the industry capital, and a

competitive fringe which owns the remaining capital,  $1 - ns$ .<sup>6</sup> We then examine the incentives of some of the fringe firms to coalesce and form a new oligopolist with capital share  $s$ . Enough capital must be held by the fringe for this to be feasible, so that  $s \leq 1 - sn$ . If this inequality is strict, then the fringe will contract but not vanish when the merger occurs.

Let  $V$  be the quantity supplied by the fringe firms, and  $X$  the total quantity supplied by the oligopolists. Fringe firms produce at output levels which equate price and marginal costs. With the horizontal summation property of the marginal cost function, this fringe equilibrium condition can be expressed simply as

$$(4) \quad P(X + V) = C_1(V, 1 - sn).$$

The quantity supplied by the fringe is implicitly defined by (4) as a function of the output of the oligopolist,  $V(X)$ .

The inverse residual demand function facing the oligopolists is then  $P(X + V(X))$ . They behave as a Stackelberg group with respect to the competitive fringe. This is a simple generalization of the dominant firm model to dominant oligopoly. The equilibrium condition for the oligopolists equates perceived marginal revenue to marginal cost, given a capital stock  $s$  for each.

The imperfectly competitive interaction of the oligopolists will be summarized by a conjectural variation. Let  $\delta$  be the conjectured output response of the other oligopolists to a unit change in own output. If  $\delta = -1$ , then the oligopolists behave competitively. Therefore, we assume  $\delta > -1$ . If  $\delta = 0$ , we have the Cournot model in which each oligopolist assumes that the others will not respond to output changes. Finally, if

<sup>5</sup>See Perry (1978) for a more complete derivation of this construction and a use of it to examine backward integration by a monopolist into a competitive upstream industry.

<sup>6</sup>The maximum size of an oligopolist could be thought of as arising from the Justice Department antitrust guidelines. (See *Merger Guidelines*, 1982.) For example, a guideline that triggered a challenge for mergers that put the industry over a 60 percent four-firm concentration ratio would imply  $s = .15$  under the assumption of symmetric oligopolists. Similarly, a Herfindahl index limit of 1600 would imply  $s = .20$  if there were four oligopolists, as  $4 \cdot (100 \cdot s)^2 = 1600$ .

$\delta = (n-1)$ , the  $n$  oligopolists act collusively to maximize joint profits. Since the fringe supply is constrained by its fixed capital stock, profitable opportunities remain for the oligopolists.

The symmetric oligopoly equilibrium output level is then given by

$$(5) \quad P + (1 + \delta) \cdot (1 + V') \cdot (X/n) \cdot P' \\ = C_1(X/n, s),$$

where  $P = P(X + V(X))$  and primes denote first derivatives. Given the cost and demand specifications of Section I, we can solve (4) and (5) to obtain the equilibrium output of the oligopolists and the fringe,

$$(6) \quad X(n) = \frac{(a-d)sn}{e + b[1 + s(1 + \delta)]},$$

$$(7) \quad V(n) =$$

$$\frac{(a-d)(1-sn)\{e + b[1 - sn + s(1 + \delta)]\}}{\{e + b[1 + s(1 + \delta)]\} \cdot [e + b(1 - sn)]}.$$

As a consequence of the linearity, the output produced by any single oligopolist,  $X(n)/n$ , is independent of  $n$ . Industry output  $Z(n)$  is the sum of  $X(n)$  and  $V(n)$ , so that

$$(8) \quad Z(n) = \frac{(a-d) \cdot K(n)}{e + b \cdot K(n)},$$

$$\text{where } K(n) = \frac{e + b(1 - sn)[1 + s(1 + \delta)]}{e + b[1 - sn + s(1 + \delta)]}.$$

Total output  $Z(n)$  is an increasing function  $K(n)$ , which is decreasing in  $n$ . Therefore, price rises as the number of oligopolists increases. This occurs because the competitive fringe becomes a smaller fraction of the industry, so that on balance the industry behaves less competitively. Without this price effect, there would be no incentive for fringe firms to merge. This occurs because a new oligopolist supplies less than did the compo-

nent share  $s$  of the fringe prior to the merger:

$$(9) \quad \frac{sV(n)}{1 - sn} - \frac{X(n+1)}{n+1} = \\ \frac{(a-d)s}{\{e + b[1 + s(1 + \delta)]\}} \cdot \frac{sb(1 + \delta)}{e + b(1 - sn)} > 0.$$

Therefore, the profits of the merged firm can exceed those of its constituent firms only if the merger results in a price rise sufficient to offset the lower output level.

In order to evaluate this incentive to merge, we compare the profits of fringe firms owning a fraction  $s$  of the capital stock,  $\pi_f(n)$ , when there are  $n$  oligopolists, with the profits of one of  $n+1$  oligopolists,  $\pi_0(n+1)$ . A fraction  $s/(1 - sn)$  of the fringe earns

$$(10) \quad \pi_f(n) = s/(1 - sn) \\ \cdot [P(Z(n)) \cdot V(n) - C(V(n), 1 - sn)],$$

while the merged firm would earn

$$(11) \quad \pi_0(n+1) = P(Z(n+1)) \\ \cdot \frac{X(n+1)}{n+1} - C\left(\frac{X(n+1)}{n+1}, s\right).$$

Since both entities incur fixed costs of  $s \cdot g$ ,  $g$  clearly has no impact on the incentive to merge. Moreover, we also discover that the comparison of profits is independent of the scaling parameters  $a$  and  $d$ . But otherwise, the incentive to merge depends upon the slope parameters  $b$  and  $e$ , and more importantly, the conjectural variation  $\delta$  and the number of firms  $n$ .

Consider the first merger. When a single oligopolist forms, we restrict  $\delta = 0$  since the oligopolist has no direct competitors. After substituting the appropriate expressions into (10) and (11), we find that  $\pi_0(1) > \pi_f(0)$  for all parameter values. Thus, there is always an incentive for a dominant firm to form from the fringe.

When  $n=1$ , a second merger could involve a movement in  $\delta$  from zero to a value in the interval  $(-1, 1)$ , as unity is the collu-

sive conjecture. We find that  $\pi_0(2) > \pi_f(1)$  if

$$(1-\delta)^2(e+b)^3 + 2(1+\delta^2)(e+b)^2bs \\ + (e+b)b^2s^2 + 2\delta b^3s^3 > 0.$$

This expression is positive for all nonnegative values of  $\delta$ . However, if  $\delta$  is sufficiently close to  $-1$ , this expression will be negative. Thus, a second firm will form from the fringe unless the resultant equilibrium is too competitive. In general, if oligopoly behavior becomes more competitive as a result of the merger, merger will be less profitable.

For  $n \geq 2$ , a comparison of equations (10) and (11) is computationally cumbersome if  $\delta$  changes with  $n$ . Thus, we hereafter assume that  $\delta$  remains unchanged after a merger occurs.

Consider now the third and subsequent mergers (obviously, we require  $s < 1/3$ ). Substituting from the functional specifications of Section I and the equilibrium quantities (6)–(8), we find that the incentive to merge can be simplified to

$$(12) \quad \pi_0(n+1) \gtrless \pi_f(n)$$

$$\text{as} \quad I(\delta, n) = -sb(1-\delta)n$$

$$+ [(1-\delta)(e+b) + sb(1+\delta)] \gtrless 0.$$

First, consider cases where  $\delta < 1$  (which includes the Cournot case where  $\delta = 0$ ). For these cases, the term  $I(\delta, n)$  is decreasing in  $n$ . Since  $I(\delta, n)$  is positive at the largest possible value of  $n$ ,  $(1/s)-1$  (where the next merger eliminates the fringe),  $I(\delta, n)$  must be positive for all relevant  $n$ . Also,  $I(1, n)$  is clearly positive. Therefore, for  $\delta \leq 1$ , there is always an incentive for an additional merger from the fringe.

For  $\delta > 1$ ,  $I(\delta, n)$  is increasing in  $n$ . Evaluating  $I(\delta, n)$  at  $n = 2$ , the smallest possible value of  $n$ , we find that it is positive for  $\delta < (e+b-sb)/(e+b-3sb)$ . For these  $\delta$ ,  $I(\delta, n)$  is positive, so there is an incentive to merge for all feasible values of  $n$  and  $\delta$  (recall that  $\delta \leq n-1$ ). Since  $(e+b-sb)/(e+b-2sb) > 1$ , this case subsumes the previous case of  $\delta \leq 1$ .

Relatively competitive behavior gives rise to an incentive to merge from the fringe. However, when  $\delta$  is less competitive, we obtain cases in which no such incentive exists. In particular, when  $I(\delta, n)$  is evaluated at the maximal value of  $n$ ,  $(1/s)-1$ , we see that there can never be an incentive to merge at any  $\delta > (e+2sb)/e$ , which also satisfies  $\delta \leq n-1$ . This leaves a range of intermediate values of  $\delta$  for which there is an incentive to merge when  $n$  is large but not when  $n$  is small. This arises because  $I(\delta, n)$  is increasing in  $n$ . We can summarize the results for  $n \geq 2$  as follows:

$$(13a) \quad \pi_0(n+1) > \pi_f(n)$$

$$\text{for} \quad \delta < (e+b-sb)/(e+b-3sb),$$

$$(13b) \quad \pi_0(n+1) \gtrless \pi_f(n)$$

$$\text{as} \quad n \gtrless \frac{(\delta-1)(e+b)-sb(1+\delta)}{sb(\delta-1)}$$

$$\text{for} \quad \frac{e+b-sb}{e+b-3sb} < \delta < \frac{e+2sb}{e} \text{ and } n \geq 1+\delta$$

$$(13c) \quad \pi_0(n+1) < \pi_f(n)$$

$$\text{for} \quad (e+2sb)/e < \delta \leq n-1.$$

The intuition for these results can best be understood by reference to Figure 1. Assume that  $b=1$ ,  $d=0$ , and  $e=s$ . Consider the incentive for the next to last merger from the fringe. The output  $OA$  is the equilibrium output of the  $n=(1/s)-2$  firms in the dominant oligopoly. Since output per firm is independent of  $n$  in this linear case,  $OA$  is also independent of the merger choice of the  $(n+1)st$  firm examined here. This leaves a residual demand curve of  $QT$  facing the fringe. The marginal cost curve for the fringe firms considering merger is  $AR$  ( $C_1(x, s) = ex/s = x$ ). This is also the supply curve of the fringe that would remain after such a merger. Thus, the residual demand facing the firms in the fringe considering merger is  $ET$ . Without merger, these firms would continue to behave competitively, produce  $BH$  at a

### III. Oligopoly of Small and Large Firms

Here we briefly consider an industry with  $n$  "large" oligopolists and  $m$  "small" oligopolists. The large oligopolists own  $s$  of the capital stock as in Section II. But instead of a competitive fringe, we assume that the remainder of the industry is composed of small oligopolists that own only  $s/2$  of the capital stock. The capital constraint  $s \cdot n + (s/2) \cdot m = 1$  must now hold. This structure provides a closer analogy to the S-S-R model in that we can examine the incentive for two small firms to merge into one large firm.

Let  $V$  be the quantity supplied by the small firms, and  $X$  the quantity supplied by the large firms. Despite their differing sizes, all firms now have the same conjectural variation  $\delta$ . Thus, the industry equilibrium can be defined by the symmetric first-order conditions for each firm size:

$$(15a) \quad P(X+V) + (1+\delta) \cdot V/m$$

$$\cdot P'(X+V) = C_1(V/m, s/2)$$

$$(15b) \quad P(X+V) + (1+\delta) \cdot X/n$$

$$\cdot P'(X+V) = C_1(X/n, s).$$

Given the cost and demand specifications of Section I, we can solve this system for the output of the two groups of firms as a function of the number of large firms  $n$ :

$$(16a) \quad X(n)$$

$$= \frac{(a-d) \cdot [b(1+\delta) + 2e/s] \cdot n}{\Delta(n)},$$

$$(16b) \quad V(n)$$

$$= \frac{2(a-d) \cdot [b(1+\delta) + e/s] \cdot [1/s - n]}{\Delta(n)},$$

where  $\Delta(n) = [b(1+\delta) + e/s] \cdot [b(1+\delta) + 2 \cdot (e+b)/s] - b^2(1+\delta) \cdot n$ . Industry output  $Z(n)$  is the sum of  $X(n)$  and  $V(n)$ , so that

$$(17) \quad Z(n)$$

$$= \frac{(a-d) \cdot [b(1+\delta)(2/s - n) + 2e/s^2]}{\Delta(n)}.$$

It is a simple matter to show that total output is a decreasing function of the number of large firms  $n$ . Thus, mergers again result in an increase in price to consumers. But unlike the previous model, firm behavior remains the same and price increases because there are now fewer firms in the industry.

The output of two small firms prior to merger is greater than output of the one postmerger firm. Thus, an incentive to merge requires that the increase in industry price be sufficient to offset the reduction in output of the merged firm. To evaluate this incentive, we simply compare the profits of one postmerger large firm,  $\pi_l(n+1)$ , with the profits of two premerger small firms,  $2 \cdot \pi_s(n)$ . The profits of each small firm before merger are

$$(18) \quad \pi_s(n) = P(Z(n))$$

$$\cdot \left[ \frac{s \cdot V(n)}{2 \cdot (1 - sn)} \right] - C \left( \frac{s \cdot V(n)}{2 \cdot (1 - sn)}, \frac{s}{2} \right),$$

while the profits of each large firm after merger are

$$(19) \quad \pi_l(n+1) = P(Z(n+1))$$

$$\cdot \frac{X(n+1)}{n+1} - C \left( \frac{X(n+1)}{n+1}, s \right).$$

Using the demand and cost assumptions of Section I and substituting from (15) and (16), we find that

$$(20) \quad \pi_l(n+1) \gtrless 2 \cdot \pi_s(n) \quad \text{as} \quad \Delta(n) \gtrless \bar{\Delta},$$

where  $\bar{\Delta} = (2b^2 \cdot q) / [2q - (q + e/s) \cdot (b(1+\delta) + q)^{1/2} \cdot q^{-1/2}]$  with  $q = b(1+\delta) + e/s$ . Since  $\Delta(n)$  is a decreasing function of  $n$ , three cases arise. First, if  $\max_n \Delta(n) = \Delta(0) < \bar{\Delta}$ , then there would always be an incentive to merge. Second, if  $\min_n \Delta(n) = \Delta((1/s) - 1) > \bar{\Delta}$  then there would never be an incentive to merge. And third, mixed cases can arise in which there is no incentive for the first mergers, but that if enough large firms already exist, there would be an incentive for the remaining small firms to merge.<sup>8</sup>

<sup>8</sup>Note that the three cases in this second model qualitatively resemble the three cases (13a)–(13c) in the

We can now illustrate that the S-S-R results generally fail to hold in our model with assets and two firm sizes. Let the conjectural variation be Cournot ( $\delta = 0$ ) as in the S-S-R model. If we then made the further S-S-R assumption that marginal costs were constant ( $e = 0$ ), conditions (15a) and (15b) would define an equilibrium with all firms being the same size. Thus, rising marginal costs ( $e > 0$ ) are necessary to define an equilibrium with differing firm sizes. Now recall that the S-S-R model yields no incentive for merger except when duopolists merge to form a monopolist. In our model when  $s = 1/2$  (small-firm duopoly), we do find that there is always an incentive to merge into one large firm.<sup>9</sup> However, our results depart considerably from those of S-S-R when  $s \leq 1/3$ , in particular, the incentive to merge often remains. When  $e > 3b$ ,  $\Delta(0) < \bar{\Delta}$  for all  $s \leq 1/3$  so that there is always an incentive to merge. Even when  $e < 3b$ , the incentive for the first merger (and thus subsequent mergers) still exists if there are few enough firms in the small oligopoly, that is, for  $s$  large enough. For  $e = 2b$ , there is an incentive for the first merger when  $s \geq 1/7$  (7 or less small firms), and no such incentive when  $s \leq 1/8$ . Similarly for  $e = b$ , there is an incentive when  $s = 1/2$  or  $1/3$ , but no incentive when  $s \leq 1/4$ . The exact S-S-R result only holds when  $e \leq b/2$ .<sup>10</sup> Note that  $e \leq b/2$  would encompass examples with  $e$  close to zero. Thus, even though the S-S-R model with  $e = 0$  has little theoretical appeal, the S-S-R results are not at variance with the limiting case of our model. However, we can generally conclude that there is a broad range of the parameters

for which there is an incentive for the first as well as all subsequent mergers.

#### IV. Conclusion

The incentive to merge depends upon a complex resolution of two forces. First, a merger results in a price increase. But second, the output of the merged firm declines relative to that of its partners prior to the merger. The price increase benefits all firms, but contrary to the results of S-S-R, it can often be sufficient to compensate for the output reduction of the merged firm and increase profits. Once one allows a merged firm to be twice as "large" as each partner, the output reduction is not nearly as severe as in the S-S-R model. However, we also find that there need not always be an incentive to merge. For the dominant oligopoly model, the conjectural variation alters this tradeoff. In particular, competitive conjectures are more conducive to merger. For the large-small oligopoly model, the incentive to merge also depends in a complex way upon demand and cost parameters.

Both models also provide a number of industry scenerios. In the dominant oligopoly model, we could find merger by the entire industry or by only the first or second firms. In the large-small oligopoly model, we could find no mergers at all. And in either model, we could find the unstable situation in which mergers would not occur unless the industry was sufficiently concentrated to begin with. Thus, even our simple models are very rich in their implications on the incentive for horizontal merger.

dominant oligopoly model. However, there is a quantitative difference in that the incentive to merge will generally be greater in the dominant oligopoly model. In that model, the  $m$  oligopolists do not expand output with a new merger; whereas the  $m$  large oligopolists in the large-small model do expand with another merger. Thus, the price increase is dampened in this second model.

<sup>9</sup>Specifically, we can easily show that  $\Delta(0) < \bar{\Delta}$  when  $\delta = 0$  and  $s = 1/2$ .

<sup>10</sup>These examples follow quickly once the relevant condition  $\Delta(0) < \bar{\Delta}$  has been simplified to  $-2b^3 - 8b^2/s - 17b^2e/s - 4b[5e^2 + 4e - 2b^2]/s^2 - 4e(e+b)(e-3b)/s^3 < 0$ . For further detail, see Section III of our 1983 working paper.

# Military Enlistments: What Can We Learn from Geographic Variation?

By CHARLES BROWN\*

Since the decision in 1973 to end the draft and return to reliance on voluntary enlistments, the number and quality of volunteers who could be attracted at politically realistic wages has been a key question. Because the armed forces adjust required qualifications when the supply of enlistees exceeds or falls short of the desired number of new recruits, the real policy issue is the availability of enlistees with desired characteristics such as a high school degree and high mental-test scores. The number of such high-quality enlistees is supply determined, but the total number of enlistees will be dominated (and perhaps determined) by recruiting targets.

It is difficult to summarize the results of previous econometric work on the supply of enlistees because the supply measure has been defined in so many ways. Some studies analyze total Defense Department enlistments, while others look at enlistments in particular services. Most focus on high-quality recruits, though "high-quality" is defined in different ways. Estimates of the elasticity of enlistments with respect to military compensation center a bit below 1.0 (Charles Dale and Curtis Gilroy, 1983; Richard Morey and John McCann, 1983). Elasticities with

respect to unemployment are much smaller; Morey and McCann's survey's range of 0.2 to 0.5 is representative. The strongest statement of the unimportance of unemployment is Colin Ash, Bernard Udis, and Robert McNown's conclusion that "The evidence on the lack of an unemployment effect on accessions is overwhelming" (1983, p. 147).

Most previous studies have used time-series data, and most of these pool pre- and post-1973 data in order to achieve an adequate sample size.<sup>1</sup> The impact of both the draft and the Vietnam war would be expected to influence supply, yet they are difficult to hold constant statistically. Because the Vietnam war years were a time of low military (relative to civilian) pay and low unemployment rates, inadequate control for the effect of the draft and the war are likely to bias estimates of the effects of military pay and civilian unemployment.

Cross-section data on enlistments and other variables in a peacetime period obviously allow one to avoid this problem. However, military pay does not vary across areas, so one must assume that the ratio of military to civilian pay (which does vary geographically) determines enlistments if one is to estimate the effect of military pay. Moreover, unmeasured differences in tastes and test scores may be correlated with civilian compensation and/or unemployment rates. For example, the historically greater propensity to enlist in the South may be due to lower civilian wage opportunities or to differences in "cultural" attitudes toward the military; failure to control for these taste differences biases the coefficients of other factors correlated with them, such as civilian pay.

When one considers the strengths and weaknesses of the time-series and cross-section

\*Department of Economics, University of Maryland, College Park, MD 20742. I have benefited from help with data sources and/or comments on a previous draft from George Abrahams, Bernard Bell, Ed Byerly, Michael Cimini, Charles Dale, Curtis Gilroy, Sandra Grove, Daniel Hamermesh, Philip Knorr, Walter Oi, Thomas Schneider, Gary Solon, Marvin Trautwein, and seminar participants at Cornell, George Washington, Maryland, Michigan State, National Bureau of Economic Research, and Virginia. Cheryl Hansen provided careful research assistance. Any remaining inadequacies are my doing. This study was financed by the U.S. Army Research Institute; additional computer support was provided by the University of Maryland Computer Science Center. The judgments expressed are mine, and should not be interpreted as reflecting the position of NBER, ARI, or the Department of Defense.

<sup>1</sup>Previous studies are discussed in more detail in my 1984 paper.

tion approaches, pooling cross-section data over the all-volunteer period emerges as an alternative worth considering. The cross-sectional dimension allows us to avoid worrying about holding constant the effects of the draft and the Vietnam war, and gives a good deal of variation in unemployment rates and some variation in civilian earnings. Pooling several cross sections allows one to introduce state-specific dummy variables to deal with state-specific differences in tastes and ability.<sup>2</sup> It also provides *some* variation in military compensation, though obviously less than would be available in longer time-series. With individual-specific intercepts, variations around state means for each of the variables over the sample period identify the coefficients, and so a short-run response is being captured.

### I. Data

The dependent variables used in this study are ratios of the number of contracts signed by male nonprior-service Army enlistees to the enlistment-age population.<sup>3</sup> Contracts cross tabulated by high school graduation and mental-test category by state for fiscal years 1976–82 were made available by the Defense Manpower Data Center. Categories (CAT) I-IIIa correspond to the top half of the test-score distribution. Four groups of recruits were analyzed: CAT I-IIIa high school graduates, all CAT I-IIIa's, all high school graduates, and all enlistees. For the first and third groups, the dependent variable is the ratio of contracts signed to number of new high school graduates in the last three years; for the other groups, it is the ratio of contracts signed to population 18–20 years of age.

Military pay is measured by basic military compensation (*BMC*), which includes the

value of allowances and tax advantages as well as base pay.

Educational benefits changed several times during the sample period. For various reasons, including the fact that such benefits are received in the future and the possibility that the benefits will not be used at all, these benefits are thought to be worth less to the recruit than their stated value. Daniel Huck, Lorin Kusmin, and Edwin Shepard (1982) calculated a range of estimates of the value of each type of educational benefit to the recruit. Using the average of the high and low estimate, the various educational benefits were combined into a single variable *ED*. If total compensation equals *BMC* plus *ED* then<sup>4</sup>

$$\begin{aligned}\ln(\text{total compensation}) \\ &= \ln(BMC) + \ln(1 + ED/BMC) \\ &= \ln(BMC) + ED/BMC.\end{aligned}$$

Military compensation consists of a large number of benefits and bonuses not included in *BMC*. Indeed, a recent study (Office of the Secretary of Defense, 1982) listed 60 categories of compensation apart from those included in *BMC*. Potential biases from ignoring these benefits can be avoided if one is willing to accept the assumption that the *ratio* of military pay to civilian pay determines enlistments. In this case, fiscal-year dummy variables can control for variations in military pay ( $W_m$ ), and the effect of both military and civilian pay determined from the coefficient of civilian pay ( $W_c$ ).

Civilian earnings  $W_c$  are measured by the quarterly average (by state) of monthly earnings of private workers, based on Unemployment Insurance (UI) records, that include nearly all private employment. The reported earnings are total earnings, not just the portion of earnings subject to UI taxes. Military and civilian pay were deflated by the Consumer Price Index.<sup>5</sup>

<sup>2</sup>Lawrence Goldberg and Peter Greenston (1983) pool time-series and cross-section data, but do not adopt the dummy-variable strategy. Instead they include the proportion black and proportion urban as controls for tastes and abilities.

<sup>3</sup>The data and data sources are described in more detail in an appendix, available from the author upon request.

<sup>4</sup>Since the *discounted ED* averaged only about 4 percent of *BMC*, the approximation  $\ln(1+x) \approx x$  is quite accurate.

<sup>5</sup>Civilian earnings were also corrected for between-state differences in living costs, using data from the

The unemployment rates used in this paper are quarterly averages of monthly unemployment rates tabulated from the *Current Population Survey (CPS)*. These were provided by the Bureau of Labor Statistics, though they emphasize that the monthly *CPS* tabulations are "official" unemployment rate estimates only for the 10 largest states. Even these unofficial tabulations were not available for about twenty of the smallest states prior to January 1976; the missing values were imputed from regressions (using 1976–82 data) which related the state unemployment rate to the national rate, the state and national employment-population ratio, and a time trend.

During this sample period, unemployment trends varied widely across regions. The unemployment rate in the Midwest as a fraction of the national average rate increased by 25 percentage points from fiscal 1976 to fiscal 1982, while those of the Northeast and West declined by 27 and 11 points, respectively. Unemployment rates in the South remained at about 90 percent of the national average throughout the period.

## II. Results

Regression results are presented in Table 1. For each dependent variable, military compensation is measured by *BMC* or a set of dummy variables. Both *OLS* and *GLS* estimates are presented.<sup>6</sup> The *GLS* estimates (that correct for first-order serial correlation) probably deserve greater weight, but the fact that the serial correlation coefficient must be estimated makes the issue less clear cut.<sup>7</sup>

---

Bureau of Labor Statistics low-income family budget series, though this correction had little impact on the estimates.

<sup>6</sup>The first-order serial correlation was estimated by the method described by Stephen Nickell (1981) and Gary Solon (1983). The equation was then quasi-first-differenced using this estimate.

<sup>7</sup>*OLS* misestimates the standard errors of coefficients in the presence of serial correlation, but in these data the standard errors changed little when *GLS* was used. *GLS* also provides smaller true standard errors when the serial correlation coefficient is known, but this gain does not necessarily occur when the correlation is estimated. In unpublished Monte Carlo experiments, Solon finds virtually no gain when using 50 cross-sectional units and 10 observations per unit when the true correlation is 0.4.

The dependent variables, *BMC*, and  $W_c$  are all entered logarithmically, so that the coefficients of *BMC* and  $W_c$  are elasticities. Given the variation in unemployment rates noted above, there seemed reason to hope that the unemployment response could be estimated with considerable precision; hence a quadratic specification was adopted. The unemployment rate is shown in percent, and coefficients of the quadratic unemployment term have been multiplied by 100. The remaining columns of the table are the coefficient of the time trend (that runs from 1 to 28), the standard error of the equation, and the elasticity of the recruiting measure with respect to the unemployment rate at the sample-mean unemployment rate of 7 percent. Not shown in the table are dummy variables for individual states,<sup>8</sup> and quarter of the year. Each state's observations were weighted by the average number of persons 18–20-years old in the state.

The dependent variable in the first four equations of Table 1 is the logarithm of the number of CAT I-III high school graduate contracts divided by the number of high school graduates. The estimated elasticity of supply with respect to military compensation is about 0.5 when *BMC* is used, but the implied elasticity is 1.0 to 1.5 when the dummy-variable approach is used. Civilian wages are negatively related to enlistments. In the equations with *BMC*, the restriction that supply is determined by the ratio of military to civilian pay (i.e., that coefficients of *BMC* and  $W_c$  be equal and opposite-signed) cannot be rejected.

The unemployment rate has very large effects on enlistment. At the mean unemployment rate of 7 percent, a one-percentage-point reduction in the unemployment rate reduces enlistments by about 10 percent. Given the difficulty of estimating unemployment effects with any precision with time-series data (see Ash, Udis, and McNown), the significance of these estimates is worth underlining.

<sup>8</sup>To reduce computational costs, the equations were actually estimated by deviating all variables from their state-specific means, which is equivalent to including state-specific dummy variables.

Note: Sample: 51 states, quarterly, from 1975:4 to 1982:3 = 1428 observations. The dependent variables are **A** = CAT I-III high school graduate contracts/high school graduates; **B** = CAT I-III contracts/population; **C** = high school graduate contracts/high school graduates; **D** = contracts/population. The *t*-statistics are in parentheses below coefficients. Each coefficient of the quadratic unemployment term is multiplied by 100.

<sup>a</sup> = *BMC*, *ED/BMC*, and *TREND* replaced by fiscal-year dummies.

The most anomalous result is the very large coefficient of *ED/BMC*. In theory, its coefficient should equal that of *BMC*; in fact, it is much larger. Part of the explanation may be that the procedure used in deriving this variable overdiscounts the value of the benefits, but it is hard to argue that this is a full explanation. In any case, since *ED/BMC* was highest when unemployment was highest in the sample period, overestimating the effect of *ED/BMC* is likely to lead to underestimating the unemployment effects.

The second set of equations focuses on the supply of CAT I-III enlistments (both

graduates and nongraduates). The conclusions that emerge are very similar to those reached for CAT I-III graduates. Compensation elasticities tend to be a bit larger, and the unemployment elasticities are a bit smaller. The unemployment elasticities remain important in practical terms.

When supply is measured by the proportion of high school graduates who enlist (third set of equations), the results are less satisfactory. Taken at face value, the first two specifications suggest that educational benefits significantly increase recruitment, but increased *BMC* reduces it. The dummy-variable specifications show quite clearly,

however, that recruitment success is inversely related to civilian alternatives, and the estimated elasticity ( $-1.1$  or  $-1.2$ ) is fairly sizeable. The effect of military compensation is just not reliably estimated in this set of equations.

Estimated unemployment elasticities, however, remain significant in both a statistical and practical sense. Moreover, they are not very sensitive to the choice of military pay specification.

The difficulties of estimating the effect of compensation on the ratio of total contracts to population is similar to that encountered in analyzing the high school graduate measure. Neither of the estimates based on explicit measures of military compensation (first two lines of this set) is plausible. The compensation elasticity of 1.85 implied by the *OLS* dummy variable specification is right-signed, but *GLS* estimation reverses this.

Although the estimated effects of unemployment on total contracts are smaller than for the other dependent variables, they are once again statistically significant and consistent across the three specifications. Given the relatively large percentage changes in unemployment rates that have occurred in the past decade, an elasticity of one-third implies nontrivial percentage changes in the number of recruits.<sup>9</sup>

<sup>9</sup>For a slightly shorter sample period (1976:4 through 1982:2), measures of recruitment effort could be included as explanatory variables. The effects of military compensation, civilian earnings, and unemployment are broadly similar to those in Table 1. The most consistent difference is a slightly smaller unemployment effect. For the three high-quality enlistee groups, the recruitment effort variables tell a generally sensible story. Additional Army recruiters increase enlistments, but increases in other services' recruiters reduce them. Proportional increases in all services' recruiters increase army enlistments. National media advertising sometimes has a positive effect, but this is unstable across specifications. Local media advertising seems to have no detectable positive effect on recruitment. One interpretation is that such advertising is concentrated on areas where enlistments are below expectations, but the limited available evidence seems inconsistent with this explanation (Morey and McCann). The estimates for all enlistees do not show a negative effect of DOD recruiters on army enlistments, but do show consistent positive national advertising coefficients.

An unavoidable question is why the compensation elasticities are more satisfactory for the first two supply measures than for the last two. While the difficulties of measuring such compensation are certainly important, the rough similarity among the alternative estimates for each of the first two measures suggest that this is an unlikely explanation for why the last two measures do not exhibit such stability. A more plausible explanation is that the number of CAT I-III A enlistees is supply determined, but the number of total enlistees is largely demand determined. The simplest story along these lines—that changes in standards offset any changes in the supply of enlistees—would predict that estimated effects would be smaller than true ones, perhaps even zero, but would not lead one to expect wrong-signed “effects.” This would seem to require that the total number of recruits demanded be negatively related to the offered wage. While military manpower demands are not usually thought of as having a significant demand elasticity in the short run, such a negative correlation could arise either by chance (recall there are only seven fiscal years of data), or because higher military compensation reduces the demand for *new* recruits by improving retention. If, in a period of excess supply, recruitment standards are raised *uniformly*, one might expect that those variables with significant geographic variation would determine how the demand-limited total of enlistments would be distributed across the country. Thus, demand constraints might be consistent not only with wrong-signed estimates for military pay, but right-signed estimates of the impacts of civilian pay and unemployment. While Arthur De Vany and Thomas Saving (1982) have modeled the way in which discrepancies between the supply of enlistees of the desired quality and the desired number of such enlistees is reconciled at the national level, there seems to be little available research on how demand constraints make themselves felt locally.

### III. Conclusions

In order to achieve an adequate sample size without including draft-period observa-

tions, and to take advantage of large regional differences in the path of unemployment in recent years, the determinants of army enlistments were estimated from quarterly data by state for fiscal years 1976–82. In sharp contrast to several previous papers, unemployment rates had quite strong effects on recruitment success. For various categories of high-quality recruits, the elasticity of contracts signed with respect to the unemployment rate ran from .4 to .8. For high-quality recruits, defined as those with scores in the top half of the distribution on the military's entrance test (or those with these scores and high school degrees), estimates of the elasticity of contracts with respect to military compensation centered *roughly* on 1.0. For total contracts and contracts signed by high school graduates (regardless of test scores), the compensation elasticity could not be estimated with any confidence. This may be because the number of such enlistments is demand constrained rather than supply determined. There was, however, consistent evidence that the number of contracts was inversely related to alternative (civilian) earnings.

The combination of sizeable unemployment elasticities and major swings in the regional concentration of unemployment had significant effects on the regional distribution of Army enlistees. During the sample period, *the Midwest replaced the South as the dominant per capita supplier of recruits to the volunteer Army.*

These results suggest that, as unemployment rates fall, the Army will have difficulty maintaining the number of high-quality recruits at currently offered compensation levels. Indeed, this adjustment has already begun: from the first half of fiscal 1983 to the first half of fiscal 1984, the unemployment rate declined from 10 to 8 percent, and unpublished U.S. Army Recruiting Command data show an 18 percent decline in the number of CAT I-III high school graduate recruits.

There are several options for dealing with this difficulty within the all-volunteer framework. The most obvious is to increase the compensation of new enlistees. A subtler strategy is to focus on retention of those

already in the Army, reducing the number of high-quality enlistees who must be recruited.<sup>10</sup> A third option is to expand the role of women. A final issue is whether the recent numbers of high-quality recruits *ought* to be maintained, since those levels were caused by the recession. This involves comparing the marginal value of relatively able individuals in military and civilian employment.

Two quite different directions for future research seem desirable, given the results of this paper. First, research on how recruiting standards respond to local or national shortages or surpluses of recruits meeting a given standard would be very useful. Second, the lag (if any) in the response of enlistments to military and civilian compensation, unemployment, etc., deserves greater attention.

<sup>10</sup> Educational benefits may be effective in encouraging new high-quality enlistments, since they are a way of paying college-eligible recruits more than others. However, because they are valuable only when one returns to civilian life, their effect on retention may be perverse. Allowing those who have earned educational benefits but remain in the military to transfer their benefits to spouses or children has been proposed as a way of blunting the disincentive to reenlist.

# Paying for Public Inputs

By RICHARD MANNING, JAMES R. MARKUSEN, AND JOHN McMILLAN\*

With public consumption goods, Pareto optimality can be achieved in equilibrium through Lindahl pricing. This requires that each consumer pays a price proportional to his marginal utility from the public good. The marginal cost of providing the good is then equated to the sum of the marginal benefits.

Some public goods serve as inputs into production processes rather than as consumption goods: the lighthouse is an example. Efficiency in an economy with public intermediate goods requires that the marginal cost of providing them equals the sum of their marginal benefits to firms. By analogy with the case of public consumption goods, it might seem that Lindahl pricing can be extended to public intermediate goods, by requiring that firms pay in proportion to the marginal contribution of these goods to profits. Agnar Sandmo (1972) explicitly proposes this for convex technologies. For nonconvex technologies that arise with an important class of production functions (essentially those exhibiting "atmosphere externalities," in the phrase of James Meade, 1952), Lindahl pricing for such public inputs is infeasible.

The principal result derived here is a simple alternative to Lindahl pricing of public inputs. This is an across-the-board tax on factor incomes at a rate that depends on production parameters. Efficiency is guaranteed if this tax is used.<sup>1</sup>

Means of paying for public inputs are discussed after the economic structure is defined in the next section. Some comments on the analysis are provided in the concluding section.

## I. The Economic Structure

Private consumption goods are produced according to

$$(1) \quad Y_i = F_i(X_i, R), \quad i = 1, \dots, n,$$

where  $Y_i$  is the output of,  $X_i \equiv (X_{i1}, \dots, X_{im})$  is a vector of private-factor inputs to, and  $F_i$  is the production function of, industry  $i$ . The variable  $R$  is the amount of public intermediate good produced and available to all firms. This good is produced from primary factors alone,

$$(2) \quad R = G(X_{n+1}),$$

where  $X_{n+1} \equiv (X_{n+1,1}, \dots, X_{n+1,m})$ , and  $G$  is the production function for public intermediate goods.

For simplicity,  $F_i$ ,  $i = 1, \dots, n$ , and  $G$  are assumed to be continuously differentiable, and  $F_{ik}$  denotes  $\partial F_i / \partial X_{ik}$ , etc. In addition,  $G$  is taken to be quasi concave and linearly homogeneous, and  $F_i$ ,  $i = 1, \dots, n$  is concave with respect to private inputs. This is, of course, the usual assumption of neoclassical general equilibrium theory. Given  $X_{n+1}$ , matters are as in that theory, therefore.

Every primary factor  $k$  is in fixed supply  $\bar{X}_k$ , so that

$$(3) \quad \sum_{i=1}^{n+1} X_{ik} = \bar{X}_k, \quad k = 1, \dots, m.$$

Efficiency in the economy described by (1), (2), and (3) requires that

$$(4) \quad r_k = p_i F_{ik}, \quad i = 1, \dots, n; \quad k = 1, \dots, m,$$

where  $r_k$  is the return to the  $k$ th private input, and  $p_i$  is the price of the  $i$ th consumption good. In addition, the Samuelson condition

$$(5) \quad \sum_{i=1}^n \frac{F_{ir}}{F_{ik}} = \frac{1}{G_k}, \quad k = 1, \dots, m$$

\*Departments of Economics; Manning: University of Canterbury, Christchurch, New Zealand; Markusen and McMillan: University of Western Ontario, London N6A 5C2 Canada.

<sup>1</sup>It is assumed that because of free entry—the public input is available for anyone to use—the industry benefiting from the public input is perfectly competitive.

must be satisfied. The efficiency conditions (4) and (5) are essentially those reached by Keimei Kaizuka (1965), Takashi Negishi (1973), and Sandmo.

With public intermediate goods there is a presumption that the production functions of the consumption-goods industries exhibit increasing returns to scale. For the case of one primary factor (called "labor"), this may be argued as follows:

With private inputs the assumption of constant returns to scale is traditionally justified by the replication of basic processes. With public inputs the concept of replication applies in the following way to production functions: doubling the number of workers in an industry, keeping the supply of the public factor fixed, leaves each worker with the same amount of the public factor to work with, so that, by the hypothesis of replication, output will double.

[Manning-McMillan, 1979, p. 246]

When there are many primary factors the argument is the same. Thus, replication implies that  $F_i$ ,  $i = 1, \dots, n$  is linearly homogeneous in the private inputs; that is,

$$(6) \quad F_i(\lambda X_i, R) = \lambda F_i(X_i, R),$$

$$\lambda > 0, \quad i = 1, \dots, n.$$

This form of production function was also used by M. Ali Khan (1980) and Thomas Pugel (1982). Clearly, (6) implies increasing returns to scale to all inputs. Means of paying for public inputs in competitive market economies when (6) applies have not been adequately discussed, so this issue is now taken up.

## II. Means of Payment for Public Inputs

Following Sandmo, the *Lindahl prices* of the public intermediate good are defined by

$$(7) \quad \pi_i = p_i F_{ir}, \quad i = 1, \dots, n.$$

Such prices generate a Pareto optimum if, for example, the production functions for

consumption goods exhibit constant returns to scale with respect to all inputs, as in Negishi and Makoto Tawada (1980). Consider, however, the problem faced by a competitive firm when (6) applies. The firm faces parametrically given prices for private goods and factors, and a given supply of the public input. It must solve

$$(8) \quad \max_{X_i \geq 0} p_i F_i(X_i, R) - \sum_{j=1}^m r_j X_{ij} - \pi_i R.$$

The following is obvious, although a proof is in order.

*Remark:* When production processes permit replication, Lindahl pricing in a competitive market economy implies that the equilibrium output of firms is zero.

### PROOF:

Suppose that  $X_i \geq 0$ .<sup>2</sup> Then (8) implies that (4) is satisfied. However, Euler's Theorem implies that

$$(9) \quad F_i(X_i, R) = \sum_{k=1}^m F_{ik} X_{ik}$$

in view of (6). Thus, profits are negative, since

$$(10) \quad p_i F_i(X_i, R) - \sum_{j=1}^m r_j X_{ij} - \pi_i R = -\pi_i R < 0.$$

But now suppose that  $X_i = 0$ . Then (6) implies

$$(11) \quad F_i(0, R) = 0.$$

This implies that

$$(12) \quad F_{ir}(0, R) = 0,$$

so that profits are zero if no inputs are used. That is

$$(13) \quad p_i F_i(0, R) - \pi_i R = 0.$$

<sup>2</sup>That is, not all private inputs are zero.

Together, (10), (11), and (13) imply that the firm has no output because it maximizes profit by using no private inputs.

This demonstrates the infeasibility of Lindahl pricing for public inputs in a competitive market economy when the technology is of a reasonable type. Notice the importance of replication in ensuring (12), and hence (13). It will now be shown that there is a simple formula for the proportional income tax rate which generates enough revenue to pay for an efficient quantity of the public input. This formula will involve the parameters

$$(14) \quad \eta_i \equiv F_{ir}R/Y_i, \quad i=1, \dots, n,$$

where  $0 \leq \eta_i \leq 1$  is the elasticity of the  $i$ th consumption-good output with respect to public good supply.<sup>3</sup> Define

$$(15) \quad \alpha_i = p_i Y_i / \sum_{i=1}^n p_i Y_i, \quad i=1, \dots, n,$$

to be the  $i$ th industry's share of the value of output of consumption goods. Further, define

$$(16) \quad \bar{\eta} \equiv \sum_{i=1}^n \eta_i \alpha_i.$$

**PROPOSITION:** *In a competitive market economy, the optimal amount of a public input is supplied if income taxes collected at the rate  $T = \bar{\eta}/(1 + \bar{\eta})$  are all spent on the public input.*

**PROOF:**

From (4) and (5) it follows that

$$(17) \quad r_j = p_i F_{ij} = \sum_{i=1}^n p_i F_{ir} G_j.$$

Thus

$$(18) \quad r_j/r_k = \sum_{i=1}^n p_i F_{ir} G_j / p_i F_{ik}.$$

Multiply through (18) by  $r_k X_{n+1,j}$  and multiply and divide the right-hand side by  $R$ . This gives

$$(19) \quad r_j X_{n+1,j} = \frac{\left( \sum_{i=1}^n p_i F_{ir} R \right) (X_{n+1,j} G_j / R)}{(p_i F_{ik} / r_k)}.$$

Notice that the definition (14) implies that

$$(20) \quad \sum_{i=1}^n p_i F_{ir} R = \sum_{i=1}^n p_i Y_i \left( \frac{F_{ir} R}{Y_i} \right) = \sum_{i=1}^n p_i Y_i \eta_i.$$

The linear homogeneity of  $G$  implies that

$$(21) \quad \sum_{j=1}^m X_{n+1,j} G_j = R.$$

Summing (19) over  $j=1, \dots, m$ , and using (4), (20), and (21) implies that<sup>4</sup>

$$(22) \quad \sum_{j=1}^m r_j X_{n+1,j} = \sum_{i=1}^n p_i Y_i \eta_i.$$

The left-hand side of (22) is the expenditure needed to produce the public input. Total income (including rents, if any, due to decreasing returns to private factors) is just

$$(23) \quad \sum_{j=1}^m r_j X_{n+1,j} + \sum_{i=1}^n p_i Y_i.$$

The assumptions of a balanced budget and a proportional income tax imply, from (22)

<sup>3</sup>Manning and McMillan introduced these parameters in their earlier paper, and showed their importance in determining the shape of production possibilities. See also Tawada and K. Abe (1984).

<sup>4</sup>If there are nonconstant returns to scale in producing public inputs, of course (21) does not hold. However, (22) can be modified by including at the right-hand side a term reflecting the departure from constant returns. This will also appear in the tax formula (24).

and (23), that

$$(24) \quad T = \frac{\sum_{i=1}^n p_i Y_i \eta_i}{\sum_{i=1}^n p_i Y_i \eta_i + \sum_{i=1}^n p_i Y_i}.$$

The definition (15) gives the tax formula from (24), on division through numerator and denominator by  $\sum_{i=1}^n p_i Y_i$ .

### III. Concluding Remarks

It is frequently argued that efficiency requires that public services be financed by direct charges on their users. It is shown here to be sometimes impossible to apply user charges. However, the proposition suggests a procedure which will work even whether or not user charges are feasible. Furthermore, the proportional tax system is administratively much more straightforward than Lindahl pricing, so it is to be preferred on that criterion as well.

While the economic structure considered here is much simplified,<sup>5</sup> it is interesting that the parameters determining the efficient tax rate are, in principle, capable of being estimated. This suggests that the conclusions reached here are of some relevance in policymaking. In this connection, it might be noted that an ad valorem sales tax, imposed on sales of the private good at the same rate as the efficient income tax, is equally good.

The problem solved in this note is similar to some found elsewhere. For instance, John Chipman (1970) provides an ideal tax-subsidy scheme for an economy with external economies of scale. In his scheme an industry is taxed (subsidized) if its elasticity of output with respect to scale is less (greater)

than the weighted average elasticity of all industries, with expenditure shares being the weights. The same, in effect, occurs in the present case. While everyone is taxed at the same rate, industries that are above average in sensitivity to public inputs gain most, so they get a net subsidy.

# Excess Labor and the Business Cycle

By RAY C. FAIR\*

In a remarkable empirical study of 168 U.S. manufacturing plants, James Medoff and Jon Fay (1985) have examined the magnitude of labor hoarding during economic contractions. They found that during its most recent trough quarter, the typical plant paid for about 8 percent more blue-collar hours than were needed for regular production work. Some of these hours were used for other worthwhile work, and after taking account of this, 5 percent of the blue-collar hours was estimated to be hoarded for the typical plant.

The hypothesis that firms may hold "excess labor" during contractions was explored in my 1969 study, using monthly three-digit industry data. A model of labor demand was developed that is based on the idea that firms may at times hold excess labor. This model was originally estimated using the monthly three-digit industry data, and it was later estimated using aggregate quarterly data. The aggregate labor demand equations are part of my U.S. macro model. The latest discussion of the aggregate equations is in chapter 4 in my 1984 study. Both the monthly industry estimates and the quarterly macro estimates support the excess labor hypothesis.

The purpose of this paper is to see if the quantitative estimates of Medoff and Fay are consistent with the aggregate estimates. If this is the case, which the results in this paper show, it provides a strong argument in favor of the excess labor hypothesis. Essentially the same conclusion has been reached using two very different data sets. This is one of the few examples in macroeconomics where a hypothesis has been so strongly confirmed using detailed micro data.

## I. Review of the Aggregate Labor Demand Equations

The latest discussion of the theoretical model upon which the labor demand equations are based is in chapter 3 of my 1984 study. Only a few features of this model will be reviewed here. The technology is assumed to be putty-clay, where at any one time there are a number of different types of machines that can be purchased. The machines differ in price, in the number of workers that must be used with each machine per unit of time, and in the amount of output that can be produced per machine per unit of time. The worker-machine ratio is assumed to be fixed for each type of machine. Adjustment costs are postulated for changes in the size of the work force and for changes in the size of the capital stock. Firms behave by maximizing the present discounted value of expected future after-tax cash flow. The main decision variables of a firm are its price, production, investment, labor demand, and wage rate. Because of the adjustment costs, it may sometimes be optimal for a firm to operate "off" its production function and hold excess labor and/or excess capital.

The transition from a theoretical to an econometric model is always difficult in macroeconomics, and the present case is no exception. This transition is discussed in chapter 4 of my 1984 study, and again only a few features will be discussed here. For the empirical work the production function is postulated to be one of fixed proportions:

$$(1) \quad Y = \min\{\lambda(J \cdot H^J), \mu(K \cdot H^K)\},$$

where  $Y$  is production,  $J$  is the number of workers employed,  $H^J$  is the number of hours worked per worker,  $K$  is the stock of capital,  $H^K$  is the number of hours each unit of  $K$  is utilized, and  $\lambda$  and  $\mu$  are coefficients that may change over time due to technical

\*Department of Economics, Yale University, New Haven, CT 06520. I am indebted to a referee for helpful comments.

progress. The variables  $Y$ ,  $J$ , and  $K$  are observed;  $H^J$  and  $H^K$  are not. This production function is only an approximation to the technology of the theoretical model. It does not allow for the existence of more than one type of machine, and it treats technical progress in an inappropriate way. Even if there were only one type of machine in existence, technical progress would take the form of machines having different  $\lambda$  and  $\mu$  coefficients depending on when they were purchased. In order to account for technical progress in this way, one would have to keep track of when each machine was purchased and what the coefficients were for that machine. This kind of detail is not possible with aggregate data, and one must resort to simpler specifications.

Given the production function, the next step is to measure the number of worker hours required to produce the output each period. This was done as follows. Output per paid-for worker hour,  $Y/(J \cdot H)$ , was first plotted for the 1952:I–1982:III period. (Data on hours paid for,  $H$ , exist, whereas data on hours worked,  $H^J$ , do not.) The peaks of this series were assumed to correspond to cases where the number of hours worked equals the number of hours paid for (i.e., where  $H^J = H$ ), which implies that values of  $\lambda$  in equation (1) are observed at the peaks. The values of  $\lambda$  other than those at the peaks were then assumed to lie on straight lines between the peaks. Given an estimate of  $\lambda$  for a particular quarter and given the production function (1), the estimate of the number of worker hours required to produce the output of the quarter (denoted  $JHMIN$ ) is simply  $Y/\lambda$ . The peaks that were used for the interpolations are 1952:I, 1953:II, 1955:I, 1966:I, 1973:I, and 1977:I. The line connecting 1973:I and 1977:I was extrapolated beyond 1977:I to fill out the series through 1982:III.

In the theoretical model, a firm's price, production, investment, labor demand, and wage rate decisions are made simultaneously in the sense that all are derived from the solution of the firm's maximization problem. For the empirical work the decisions are assumed to be made sequentially, where the sequence is price, production, investment,

labor demand, and wage rate. The labor demand equations are thus based on the assumption that the production decision has already been made. Were it not for the adjustment costs of changing employment, the optimal level of employment would merely be the amount needed to produce the output of the period, but, because of these costs, excess labor may be held during certain periods. In the theoretical model there was no need to postulate explicitly how employment deviates from the amount required to produce the output, but this must be done for the empirical work.

The estimated demand-for-workers equation is based on the following three equations:

$$(2) \quad \Delta \log J = \alpha_0 \log \frac{J_{-1}}{J_{-1}^*} + \alpha_1 \Delta \log Y \\ + \alpha_2 \Delta \log Y_{-1} + \alpha_3 \Delta \log Y_{-2},$$

$$(3) \quad J_{-1}^* = JHMIN_{-1}/H_{-1}^*,$$

$$(4) \quad H_{-1}^* = \bar{H}e^{\delta t},$$

where  $JHMIN$  is the number of worker hours required to produce the output of the period,  $H^*$  is the average number of hours per worker that the firm would like to be worked if there were no adjustment costs, and  $J^*$  is the number of workers the firm would like to employ if there were no adjustment costs. The term  $\log(J_{-1}/J_{-1}^*)$  in equation (2) will be referred to as the (logarithmic) "number of excess workers" on hand. Equation (2) states that the change in the demand for workers is a function of the number of excess workers on hand and three change-in-output terms (all changes are changes in logs). If output has not changed for three periods and if there are no excess workers on hand, the change in workers employed is zero. The change-in-output terms are means in part to be proxies for expected future output changes. Equation (3) defines the desired number of workers, which is simply equal to the required number of worker hours divided by the desired number of hours worked per worker. Equation (4) postulates that the desired number of hours worked is a smoothly

trending variable, where  $\bar{H}$  and  $\delta$  are constants.

Combining equations (2)–(4) yields

$$(5) \quad \Delta \log J = \alpha_0 \log \bar{H} \\ + \alpha_0 \log \frac{J_{-1}}{JHMIN_{-1}} + \alpha_0 \delta t + \alpha_1 \Delta \log Y \\ + \alpha_2 \Delta \log Y_{-1} + \alpha_3 \Delta \log Y_{-2}.$$

This equation was estimated by two-stage least squares under the assumption of first-order serial correlation of the error term for the 1954:I–1982:III period. The estimated equation is ( $t$ -statistics in absolute value are shown in parentheses):<sup>1</sup>

$$(6) \quad \Delta \log J = -.885 - .141 \log \frac{J_{-1}}{JHMIN_{-1}} \\ (3.76) \quad (3.75) \\ + .000176t + .281 \Delta \log Y \\ (4.28) \quad (8.33) \\ + .119 \Delta \log Y_{-1} + .033 \Delta \log Y_{-2} \\ (3.03) \quad (1.02) \\ - .00967 D593 + .00174 D594 \\ (2.70) \quad (0.50)$$

$$SE = .00355, R^2 = .780, D-W = 2.04, \hat{\rho} = .447 \\ (4.44)$$

where  $D593$  and  $D594$  are dummy variables for the 1959 steel strike. The estimated value of  $\alpha_0$  is  $-.141$ , which means that, other things being equal, 14.1 percent of the number of excess workers on hand is eliminated each quarter. The implied value of  $\bar{H}$  is 531.97, which at a weekly rate is 40.92 hours. The implied value of  $\delta$  is  $-.00125$ . The trend variable  $t$  is equal to 9 for the first quarter of the sample period (1954:I), and so the implied value of  $H_{-1}^*$  for 1954:I at a weekly rate is  $40.92 \cdot \exp(-.00125 \times 9) = 40.46$ . For 1982:III,  $t$  is equal to 123, and so

the implied value for this quarter is  $40.92 \cdot \exp(-.00125 \times 123) = 35.09$ . In general these numbers seem reasonable.

The estimated demand-for-hours equation is based on equations (3), (4), and the following equation:

$$(7) \quad \Delta \log H = \lambda \log(H_{-1}/H_{-1}^*) \\ + \alpha_0 \log(J_{-1}/J_{-1}^*) + \alpha_1 \Delta \log Y.$$

The first term on the right-hand side of equation (7) is the (logarithmic) difference between the actual number of hours paid for per worker in the previous period and the desired number. The reason for the inclusion of this term in the demand-for-hours equation but not in the demand-for-workers equation is that, unlike  $J$ ,  $H$  fluctuates around a slowly trending level of hours. This restriction is captured by the first term in (7). The other two terms are the number of excess workers on hand and the current change in output. Both of these terms have an important effect on the demand-for-workers decision, and they should also affect the demand-for-hours decision since the two decisions are closely related. Past output changes might also be expected to affect the demand-for-hours decision, but these were not found to be significant and so are not included in (7).

Combining (3), (4), and (7) yields

$$(8) \quad \Delta \log H = (\alpha_0 - \lambda) \log \bar{H} \\ + \lambda \log H_{-1} + \alpha_0 \log \frac{J_{-1}}{JHMIN_{-1}} \\ + (\alpha_0 - \lambda) \delta t + \alpha_1 \Delta \log Y.$$

The estimated equation is

$$(9) \quad \Delta \log H = 1.37 - .284 \log H_{-1} \\ (4.95) \quad (5.16) \\ - .0659 \log \frac{J_{-1}}{JHMIN_{-1}} - .000250t \\ (3.55) \quad (4.94) \\ + .120 \Delta \log Y \\ (4.40)$$

$$SE = .00285, R^2 = .398, D-W = 2.18.$$

The estimated value of  $\lambda$  is  $-.284$ , which

<sup>1</sup>The first-stage regressors that were used for this work are presented in Table 6-1 in my earlier study (1984). The same holds for equation (9) below.

means that, other things being equal, actual hours per worker are adjusted towards desired hours by 28.4 percent per quarter. The excess workers variable is significant, with an estimated value of  $\alpha_0$  of  $-.0659$ . The implied value of  $\bar{H}$  is 534.60, which is 41.12 hours at a weekly rate. This compares closely to the value of 40.92 implied by equation (6). The implied value of  $\delta$  is  $-.00115$ , which compares closely to the value of  $-.00125$  implied by equation (6). No attempt was made to impose the restriction that  $\bar{H}$  and  $\delta$  are the same in equations (6) and (9). Given the closeness of the estimates, it is unlikely that imposing this restriction would make much difference.

The significance of the excess workers variable in equations (6) and (9) provides support for the excess labor hypothesis. It seems unlikely that a variable like this would be significant if firms never or seldom held excess labor.

## II. Comparison

The main concern of this paper is whether the above aggregate empirical results are consistent with the Medoff-Fay micro results. Before making this comparison, various concepts of "excess" labor need to be reviewed. Medoff and Fay distinguish between regular production work and other work. Much of the other work is maintenance. They find that at its trough in output the typical plant paid for about 8 percent more hours than were needed for regular production work. About 3 of this 8 percent was used for worthwhile other work, which means that about 5 percent of the hours was truly hoarded. Firms appear to shift at least some maintenance work from high-output to low-output periods.

For the aggregate work above there is no distinction between regular production work and other work. Within this framework there are two concepts of excess labor. One is  $J/J^*$ , which is the ratio of the actual number of workers to the long-run desired number. The other is  $(J \cdot H)/JHMIN$ , which is the ratio of total worker hours paid for to the total number required to produce the output. Note that  $J/J^*$  equals  $(J \cdot H^*)/JHMIN$ ,

where  $H^*$  is the long-run desired number of hours worked per worker.  $J/J^*$  measures how far the firm is from its long-run desired number of workers. It seems to be the appropriate "excess labor" variable to use in the labor demand equations, and it has been so used.  $(J \cdot H)/JHMIN$ , on the other hand, measures the number of hours paid for but not worked, and it seems to be the appropriate variable to compare to the Medoff-Fay estimates. It will be called the "percentage of excess hours."

If maintenance work is shifted from high- to low-output periods, then  $JHMIN$  is a misleading estimate of worker hour requirements. In a long-run sense,  $JHMIN$  is too low because it has been based on the incorrect assumption that the peak productivity values could be sustained over the entire business cycle. This error is not a serious one from the point of view of estimating the labor demand equations (6) and (9) above. If the same percentage error has been made at each peak, which is likely to be approximately the case, the error will merely be absorbed in the estimates of the constant term in the two equations. It does mean, however, that  $(J \cdot H)/JHMIN$  should not be compared to the Medoff-Fay concept of hoarded hours (i.e., to the 5 percent number). It is likely to be closer to the Medoff-Fay concept of hours in excess of regular production work (i.e., to the 8 percent number). The 8 percent number, like the peak-to-peak interpolation work, does not account for maintenance that is shifted from high- to low-output periods.

One final point should be noted before making the comparison. The aggregate estimates are based on the assumption of constant short-run returns to labor. If there are in fact decreasing short-run returns, then, other things being equal,  $JHMIN$  will overestimate worker-hour requirements in low-output periods. This is because in off-peak output periods the values of  $\lambda$  estimated from the peak-to-peak interpolations will be lower than the true values. The Medoff-Fay results show some evidence in favor of decreasing returns to labor. The results are not very strong, however, and they do not put any stress on them. There is no obvious way

TABLE 1—ACTUAL AND PREDICTED VALUES OF  $(J \cdot H)/JHMIN$ 

Quarter	Actual	Predicted	Quarter	Actual	Predicted	Quarter	Actual	Predicted
54:I	1.022	1.020	63:III	1.026	1.026	73:I	1.000	1.009

63:II	1.035	1.029	72:IV	1.011	1.017	82:II	1.050	1.041
						82:III	1.047	1.040

Note: Root mean squared error = .011. The predicted values are from a dynamic simulation that begins in 1954:I. The model consists of equations (6) and (9).  $Y$  and  $JHMIN$  ( $= Y/\lambda$ ) are exogenous.

to test the constant returns hypothesis using the aggregate data, and so it has simply been assumed to be true. One should be aware, however, that  $JHMIN$  will be biased upward if there are decreasing returns.

One thing that can be done to compare the results is simply look at the actual values of  $(J \cdot H)/JHMIN$  over the business cycle. Another is to see what the model predicts these values to be. This information is presented in Table 1. The model consists of

equations (6) and (9).  $Y$  and  $JHMIN$  ( $= Y/\lambda$ ) are exogenous. The predicted values in Table 1 are for a dynamic simulation for the 1954:I–1982:III period. The results in Table 1 show, first of all, that the model fits the data well. The predicted values are based on a dynamic simulation of 115 quarters in length, and the root mean squared error over the entire period is only .011.

Consider now the actual values in Table 1. There are two possible troughs that are rele-

TABLE 2—PREDICTED VALUES OF  $(J \cdot H)/JHMIN$  FOR ALTERNATIVE OUTPUT PATHS

Quarter	Output Change	$\frac{J \cdot H}{JHMIN}$ Change	Output Change	$\frac{J \cdot H}{JHMIN}$ Change	Output Change	$\frac{J \cdot H}{JHMIN}$ Change
78:I	-1.0	.61	-2.0	1.22	-4.0	2.48
78:II	-2.0	.97	-4.0	1.99	-8.0	4.12
78:III	-3.0	1.26	-6.0	2.58	-8.0	2.67
78:IV	-4.0	1.49	-8.0	3.10	-8.0	2.08
79:I	-4.0	1.07	-8.0	2.20		

Notes: Output Change =  $100 \cdot ((\text{new } Y / \text{old } Y) - 1)$ ;

$(J \cdot H)/JHMIN$  Change =  $100 \cdot (\text{new } J \cdot H / JHMIN / \text{old } J \cdot H / JHMIN - 1)$ .

vant for the Medoff-Fay study, the one in mid-1980 and the one in early 1982. The first survey upon which the Medoff-Fay results are based was done in August 1981, and the second (larger) survey was done in April 1982. A follow-up occurred in December 1982. The plant managers were asked to answer the questionnaire for the plant's most recent trough. For the last responses the trough might be in 1982, whereas for the earlier ones the trough is likely to be in 1980. Table 1 shows that in 1980 the percentage of excess hours reached a high of 4.5 percent in the fourth quarter. In 1982 it reached a high of 5.5 percent in the first quarter. The percentages in earlier troughs are 5.4 in 1958:I, 8.4 in 1960:IV, 5.3 in 1970:I, and 4.5 in 1974:IV.

The Medoff-Fay estimate of 8 percent is thus compared to the 4.5 and 5.5 percent values in Table 1 for the two most recent trough quarters. These two sets of results seem consistent. There are at least two reasons for expecting the Medoff-Fay estimate to be somewhat higher. First, the trough in output for a given plant is on average likely to be deeper than the trough in aggregate output, since not all troughs are likely to occur in the same quarter across plants. (In the aggregate model, other things being equal, the deeper the trough, the larger will be the predicted percentage of excess hours, and the comparison of the two sets of results has not adjusted for different size troughs.) Second, the manufacturing sector may on average face deeper troughs than do other sectors, and the aggregate estimates in Table 1 are for the total private sector, not just manufac-

turing. One would thus expect the Medoff-Fay estimate to be somewhat higher than the aggregate estimates, and 8 percent versus a number around 5 percent seems consistent with this.

With respect to the predicted values in Table 1, in 1980 the predicted percentage of excess hours reached a high of 4.4 percent in the second quarter, and in 1982 it reached a high of 4.8 percent in the first quarter. These values compare fairly closely to the actual values.

One cannot get from the Medoff-Fay results estimates of the timing of the response of excess hours to output fluctuations. This can be done, however, with the aggregate equations. The results of three experiments are reported in Table 2. These experiments were performed as follows. First, the estimated residuals were added to equations (6) and (9) and treated as exogenous. This means that when the model is solved using the actual values of  $Y$ , perfect fits are obtained for  $J$  and  $H$  (and thus  $J \cdot H$ ). Second,  $Y$  was changed and the model was solved for the new values of  $Y$ . Third, the new (predicted) values of  $J \cdot H / JHMIN$  were compared to the old (actual) values to see the response of excess hours to the output changes. The simulation period began in 1978:I. All three simulations were dynamic. For the first experiment  $Y$  was lowered (from its actual value) by 1.0 percent in the first quarter, 2.0 percent in the second, 3.0 percent in the third, and 4.0 percent in the fourth and fifth. The second experiment was the same as the first except that the decreases were twice as large. For the third experiment  $Y$  was lowered

by 4.0 percent in the first quarter and 8.0 percent in the second, third, and fourth.

The results in Table 2 show that, for the first experiment, excess hours reached a high of 1.49 percent in the fourth quarter. For the second experiment, the high was 3.10 percent in the fourth quarter. The values for the second experiment are only slightly more than twice as large as the values for the first, which means that the excess-hours response to output fluctuations is not very nonlinear with respect to the size of the changes. The response is, however, quite nonlinear with respect to the timing of the changes. For the third experiment compared to the second experiment, output was 8 percent lower by the second quarter rather than by the fourth quarter. Excess hours reached a high of 4.12 percent for the third experiment compared to a high of 3.10 percent for the second experiment.

Remember, of course, that these results are based on the particular specification of the aggregate model. If there are, for example, decreasing short-run returns to labor, then the increase in excess labor due to the fall in output will have been underestimated. Also, the model does not account for the possibility that the response of firms in eliminating excess labor is larger the larger is the fall in output. If firms begin to decrease employment drastically for very large downturns, the percentage of excess labor may actually fall as downturn size increases, and the model is not capable of capturing this. It

is unlikely that one would be able to pick up a response shift like this in the aggregate data.

### III. Conclusion

The Medoff-Fay results seem consistent with the aggregate estimates, which is further evidence in favor of the excess labor hypothesis. This hypothesis has important implications for the production function and investment literature. Much of this literature is based on the assumption that firms are always "on" their production functions. If they are not and if in fact the amount of worker hours hoarded during contractions, even after adjusting for worthwhile nonproduction work, is as much as 5 percent of total worker hours, it is not clear that estimates of production parameters and investment behavior that are based on the assumption of no hoarding are trustworthy.

# Monopoly Unionism: Note

By DANIEL LÉONARD\*

Edward Lazear (1983) presents a model in which the number of unionized workers in an industry is endogenously determined by the utility-maximizing workers themselves. Hence in his model union firms and non-union firms coexist. He assumes that the nonunion wage adjusts so that the labor market clears and full employment prevails.

The purpose of this note is to examine the possibility of unemployment in Lazear's model. Of all the possible rigidities in the labor market that could lead to unemployment, the most natural one is the existence of minimum wage legislation.<sup>1</sup> It will be shown that the imposition of a minimum wage may induce the formation of a union. Furthermore, an increase in the minimum wage will result in a higher union wage, but decrease aggregate wage income. Finally, I investigate the influence of the elasticity of demand for labor on some indicators of union power.

Henceforth it will be assumed that firms cannot pay a wage below some specified level  $\bar{W}$ . This entails some modification of Lazear's model which is now briefly presented. The variables  $W_u$  and  $W_N$  are the union wage and the nonunion wage, respectively.  $C_i$  is the cost to firm  $i$  of blocking unionization of its workforce with  $C_i \sim g(C_i)$  and  $G(C)$  the probability that firm  $i$ 's blocking cost does not exceed  $C$ ; apart from this disparity in blocking costs, all firms are identical.  $d(W)$  is the demand for labor by a firm faced with wage  $W$  and  $\Pi(W)$  is its profit outside of blocking costs. Define  $\Pi^*(W_u, W_N) \equiv \Pi(W_N) - \Pi(W_u)$  and firm  $i$  will block unionization when  $\Pi^*(W_u, W_N) > C_i$ , hence the probability that a firm will block is  $G[\Pi^*(W_u, W_N)]$ . The number of firms is  $S$

and  $R$  is the number of workers. The labor market equilibrium condition (1) of Lazear must be modified as

$$(1a) \quad S[1 - G[\Pi^*(W_u, W_N)]]d(W_u) + S[G[\Pi^*(W_u, W_N)]]d(W_N) - R \leq 0,$$

$$(1b) \quad W_N - \bar{W} \geq 0,$$

(1c) The product of the left-hand sides of (1a) and (1b) vanishes,

$$(1d) \quad W_u \geq W_N.$$

These equations define the union's opportunity locus depicted as a thick line in Figure 1. The probability that a worker will be employed at the union wage is

$$P \equiv (S/R)[1 - G[\Pi^*(W_u, W_N)]]d(W_u).$$

The probability that a worker will be employed at the nonunion wage is

$$Q \equiv \begin{cases} (S/R)[G[\Pi^*(W_u, \bar{W})]]d(\bar{W}) & \text{if } W_N = \bar{W} \\ 1 - P & \text{if } W_N > \bar{W} \end{cases}$$

The probability that a worker will be unemployed is  $(1 - P - Q)$ ; note that this is zero when  $W_N > \bar{W}$ .

Denoting the union fee by  $Z$  each worker chooses  $W_u$  and  $W_N$  to maximize

$$(2) \quad K = P(W_u - Z) + Q(W_N) + (1 - P - Q)(0),$$

subject to (1).

In the case where (1b) is not binding while (1a) is, the analysis of Lazear applies without change. Hereafter I analyze the case where (1a) is not binding while (1b) is; then the worker's problem reduces to choosing  $W_u$  to

\*Department of Econometrics, University of New South Wales, P.O. Box 1, Kensington, N.S.W. 2033, Australia. I am grateful to Edward Lazear for a constructive suggestion.

<sup>1</sup>Jacob Mincer (1981) addresses the minimum wage problem in a somewhat similar vein.

FIGURE 1

maximize

$$\begin{aligned}
 K &= (S/R)[1 - G[\Pi^*(W_u, \bar{W})]]d(W_u) \\
 &\quad \times (W_u - Z) + (S/R) \\
 &\quad \times [G[\Pi^*(W_u, \bar{W})]]d(\bar{W})\bar{W}, \\
 K &= (S/R)[G[\Pi^*(W_u, \bar{W})]] \\
 &\quad \times [d(\bar{W})\bar{W} - d(W_u)(W_u - Z)] \\
 &\quad + d(W_u)(W_u - Z)].
 \end{aligned}$$

A solution to this problem must satisfy the first-order condition,

$$\begin{aligned}
 (dG/dW_u)[d(\bar{W})\bar{W} - d(W_u)(W_u - Z)] \\
 + (1 - G)[d'(W_u)(W_u - Z) + d(W_u)] = 0.
 \end{aligned}$$

But  $dG/dW_u = G'(\partial\Pi^*/\partial W_u) = G'd(W_u)$  from duality theory, and the first-order condition can be stated as

$$\begin{aligned}
 (3) \quad (1 - G)[d'(W_u)(W_u - Z) + d(W_u)] \\
 - G'd(W_u)[d(W_u)(W_u - Z) - d(\bar{W})\bar{W}] = 0
 \end{aligned}$$

This maximum is situated at point *A* in Figure 1. Condition (3) can be interpreted as follows: the first term is the product of the

rate of increase in union revenue per firm, and of the proportion of unionized firms; the second term is the product of the additional total wage payment made by a union firm over that made by a nonunion firm, and of the rate of increase in the proportion of nonunion firms. At the optimum the expected gain from increasing  $W_u$  (while remaining employed by a union firm) is exactly offset by the expected loss due to increased militancy of firms and the subsequent increase in the number of nonunion firms.

Let us now consider the effect of an increase in the minimum wage rate on the level of the union wage. At a maximum the sign of  $dW_u/d\bar{W}$  is given by the partial derivative of (3) with respect to  $\bar{W}$ :

$$\begin{aligned}
 A &\equiv G'd(\bar{W})[d'(W_u)(W_u - Z) + d(W_u)] \\
 &\quad + G''d(\bar{W})d(W_u)[d(W_u)(W_u - Z) \\
 &\quad - d(\bar{W})\bar{W}] \\
 &\quad + G'd(W_u)[d'(\bar{W})\bar{W} + d(\bar{W})].
 \end{aligned}$$

Using (3) we obtain,

$$\begin{aligned}
 A &= [d'(W_u)(W_u - Z) + d(W_u)]d(\bar{W}) \\
 &\quad \times (1 - G)[G'/(1 - G) + G''/G'] \\
 &\quad + G'd(W_u)[d'(\bar{W})\bar{W} + d(\bar{W})].
 \end{aligned}$$

The first and last brackets in *A* are marginal revenues to be extracted from a firm by workers; clearly wage claims (and a fortiori  $\bar{W}$ ) will not be pushed past the point where they yield negative returns. Therefore a sufficient (but not necessary) condition for *A* to be positive is  $[G'/(1 - G) + G''/G'] \geq 0$ . This condition restricts only the distribution of the costs of union blocking among firms; if it is satisfied we say that the distribution of these costs is "regular."<sup>2</sup>

<sup>2</sup>It is clearly possible to find distributions that violate this regularity condition so that the result may not hold. However, this is only possible when *g* is decreasing and thus, for unimodal distributions, restricts only the upper tail. The mildness of the condition can be better grasped

FIGURE 2

**PROPOSITION 1:** *If blocking costs are regularly distributed, the imposition of or an increase in the minimum wage will raise the union wage, decrease employment in both sectors, and decrease aggregate wage income (hence the expected income of each worker). The larger the increase in the minimum wage, the stronger are these effects.*

Most of Proposition 1 follows directly from the above argument. The reason why aggregate wage income decreases with  $\bar{W}$  is that  $K$  is the average wage income; therefore any further tightening of the minimum wage constraint lowers the attainable maximum  $K$ .

Since this result holds in all cases where the minimum wage constraint is binding, we can draw the locus of equilibrium points as  $\bar{W}$  rises; it is depicted by the dotted line in Figure 1. Proposition 1 implies that minimum wage legislation has little to recommend it: firms' profits, average worker's income, and output all fall as a result. The only unambiguous beneficiaries are union workers still employed after the change (non-union workers who are still employed may

have been union workers previously). The argument often proffered in defense of a minimum wage that it is the lowest "living" wage is not tenable in this model in view of the possibility that some workers are unemployed.

Lazear correctly points out (p. 634) that if the critical indifference curve (which yields the same utility as that derived in competitive equilibrium) does not intersect the opportunity locus, a union equilibrium fails to exist, that is, all workers receive the competitive wage (denoted by  $W_c$  in Figure 1). The introduction of a minimum wage has a powerful implication for this existence question. Clearly, if  $\bar{W}$  is large enough so that the critical indifference curve intersects the line  $W_N = \bar{W}$ , a union equilibrium will occur.

**PROPOSITION 2:** *The imposition of a high enough minimum wage will result in the formation of a union sector in an industry with a previously competitive labor market.*

Obviously, the policy implications of these results depends on the empirical validity of the model; thus it is tempting to attempt to test it by examining whether the unionized sector has grown after the introduction of minimum wage legislation in various states. It is comforting to note that unions have typically been staunch supporters of a minimum wage, as predicted by this note.

One finding reported by Lazear is that "Contrary to Marshall, inelasticity of the demand for labor does not imply an increase in union power as measured by either an increase in union membership or the union/nonunion wage differential" (p. 631). I now show that when the minimum wage constraint is binding, the wage differential unmistakably increases with the inelasticity of the demand for labor. The explanation for this reversal lies in the fact that while in Lazear's model the secondary effect of an increase in the union wage was to reduce the nonunion wage thereby making the net effect ambiguous (see p. 636), no such occurrence is possible when the nonunion workers receive the minimum wage.

Let us consider small changes in the elasticity of demand for labor, denoted by  $E > 0$ ,

with the help of Figure 2. The length  $L$  is defined by  $L = -G'/G''$  and

$$G'/(1-G) + G''/G' = (G'L/(1-G) - 1)/L \geq 0.$$

Thus the regularity condition requires that the area under the upper tail does not at any point exceed the area of the rectangle that has the tangent to  $g$  as its diagonal. It is obvious that this is true of concave, linear, or mildly convex functions.

starting from the equilibrium position defined by (3) which can be rewritten as

$$(4) \quad (1-G)[1-E(W_u-Z)/W_u] - G'[d(W_u)(W_u-Z)-d(\bar{W})\bar{W}] = 0.$$

At a maximum the sign of  $dW_u/dE$  is given by the partial derivative of (4) with respect to  $E$ :

$$B \equiv -(1-G)(W_u-Z)/W_u < 0.$$

Therefore  $dW_u/dE < 0$ .

However, the effect of a higher wage on other indicators of union power is negative as shown:

$$\begin{aligned} dP/dE &= (dP/dW_u)(dW_u/dE) \\ &= (S/R)[d'(W_u)(1-G) \\ &\quad - G'(d(W_u))^2](dW_u/dE) > 0, \end{aligned}$$

and

$$\begin{aligned} dQ/dE &= (dQ/dW_u)(dW_u/dE) \\ &= (S/R)G'd(W_u)d(\bar{W})(dW_u/dE) \\ &< 0. \end{aligned}$$

Let total net pay of union workers be denoted by  $T \equiv RP(W_u - Z)$ .

$$T = S(1-G)d(W_u)(W_u-Z)$$

$$\begin{aligned} dT/dE &= (dW_u/dE)S[(1-G) \\ &\quad \times [d'(W_u)(W_u-Z) + d(W_u)] \\ &\quad - G'(d(W_u))^2(W_u-Z)]. \end{aligned}$$

Using (3) this simplifies to

$$\begin{aligned} dT/dE &= -SG'd(W_u)\bar{W}d(\bar{W})(dW_u/dE) \\ &> 0. \end{aligned}$$

**PROPOSITION 3:** *When nonunion workers receive the minimum wage, the inelasticity of the demand for labor increases the union wage, decreases the proportion of union workers, and increases that of nonunion workers. It also decreases the total net pay of union workers.*

Hence we would expect to find fewer union firms and a higher union/nonunion wage differential in industries with a more inelastic labor demand.

Although these predictions are quite clear, they affect union power in opposite ways. On the whole, I would argue that a smaller total net pay for the union membership means a weaker union and beg to differ from Marshall in this case.

# Why Everything Takes 2.71828... Times as Long as Expected

By PHILIP MUSGROVE\*

It is widely observed, and almost as widely lamented, that everything takes longer than one expects. However, most attempts to explain why deadlines are missed and budgets overrun go no farther than Murphy's (n.d.) often-quoted aphorism. Blaming the phenomenon on unrealistic expectations, as Handtvefer (1982) does, cannot explain why expectations are not revised after repeated disappointment. The problem presents both a theoretical challenge to economic science and an issue of great practical importance; a procedure for predicting delays could save a lot of money and frustration. In the absence of constraints on the time available for a job, it turns out that the ratio of time taken to time expected tends to  $e = 2.71828...$  for a job consisting of an infinite number of steps. Shorter jobs exceed the expected time by ratios less than  $e$  but never less than 2. Constraints on time, when the time available is less than what is expected to be needed for completion, only make matters worse.

## I. Delays in Steps and in Jobs

A "job" is just something one wants to get done—and can tell whether it has been finished or not. A "step" is a physically essential part of a job, performed in sequence with other steps; completing the last step means finishing the job. To avoid considering intervals between steps, a step is not regarded as finished until the next step is begun.

The first question then is, how does delay in a step affect the job of which the step is a part? Procrastinateur (1971) appears to have been the first to show that a delay in one step introduces an equal proportional, rather than absolute, delay in the entire project. Study-

ing 283 large civil engineering projects,<sup>1</sup> in each of which one step triggered delay in the job, he found that a one-month step delay could slow down the project by as much as two years, even when nothing else went exogenously wrong. I have obtained very similar results using a large sample from the *PAO Register* (1969 et seq.), which includes military as well as civilian projects discriminated by presidential administration, cabinet agency or contractor responsible, and the state in which the project occurred. None of these variables is significant.<sup>2</sup>

These results can be summarized in

**PROPOSITION 1:** *If  $S$  and  $P$  are step and project time, respectively, and  $DS$  and  $DP$  are step and project delays, then*

$$1 + DP/P = \prod_{i=1}^N (1 + DS_i/S_i)$$

where  $i = 1, 2, \dots, N$  are the project steps.

## II. Number of Steps and Step Delays

The finding that job delays are proportional to step delays is initially counterintuitive, but is plausible once one considers that the delayed step interrupts the schedule of work, causes overtime or stretch-outs to avoid overtime, and even produces delays in previously executed steps which have to be tested or repeated to make sure they do not suffer the same error which caused the delay. Procrastinateur's research also suggests that job delay does not depend on where in the project the delayed step or "foul-up" occurs,

<sup>1</sup>All of them, to be sure, designed and executed by Frenchmen.

<sup>2</sup>When highway projects alone are studied, the dummy for Massachusetts is almost significant ( $t = 1.83$ ).

\*The Brookings Institution, 1775 Massachusetts Avenue, NW, Washington, D.C. 20036.

contradicting Harnischfeger's (1976) hypothesis that delays hurt most if they happen near the beginning or end of a project.<sup>3</sup> A still more puzzling result is that the complexity or differentiation of the steps does not seem to matter: this contradicts the intuitive notion that a step is a quite arbitrary element of a project, and that complex steps can be made into simple ones by subdivision. This should permit better control and less delay, but if simple and complicated steps are equally dangerous as sources of delay, nothing can be gained by adding to the number of steps. A project such as raising a pyramid, in which each step consists of placing a single stone but some are harder to seat than others, might offer a test of this issue. Unfortunately, Bloch's (1948) estimates of delays due to fractures and accidents at Giza are hotly disputed by other scholars, and anyway are too vague for quantitative analysis.<sup>4</sup>

Procrastinateur did not include the number of steps in his analysis, but when it is included, the apparent paradox disappears. Smythe (1976), studying the limits on the division of labor in manufacturing, discovered that step delay tends to be inversely proportional to the number of steps in a process, confirming that subdivision of labor yields a gain at the level of individual steps. Her results give

**PROPOSITION 2:**  $E(DS/S) = 1/N$ , with  $\text{var}(DS/S)$  of order  $1/N^2$ .

Combining Propositions 1 and 2 then establishes

**THEOREM 1:** *As a job is continuously subdivided into steps, the time actually taken to complete it tends to  $e$  times the time anticipated for its completion.*

<sup>3</sup>Harnischfeger's hypothesis, while incorrect for delays, may still be valid for "step problems" of other types—for example, if the job is an airplane flight, with takeoff the first step and landing the last one.

<sup>4</sup>Bloch sometimes relies on the number of days the Pharaoh spent sulking, which, even if correctly reported by the scribes, is a poor proxy for delay in construction.

#### PROOF:

It is straightforward: substitution of Proposition 2 into Proposition 1 gives:

$$\begin{aligned} \text{Time Required/Time Expected} \\ &= R_N = (1 + 1/N)^N \\ \text{and } \lim R_N &= e, \text{ as } N \rightarrow \infty. \end{aligned}$$

Passing to the limit removes the arbitrariness in the definition of a step. The ratio nevertheless converges: a job of arbitrarily many steps does not take forever to complete, in accord with experience.<sup>5</sup> It is an immediate corollary that even a job of only one step takes on average twice as long to finish as expected, since  $N=1$  means  $R_N = 2$ .

#### III. Time Required and Time Available

Suppose  $A$  is the total time available for a job (exogenously determined by the "boss"), and that the average anticipated time required for a step is  $T$ , so that  $NT$  is the total time the job is expected to take. Define  $m = NT/A$  as the share of the available time that the job is expected to use. If  $N$  and  $A$  tend to infinity at the same rate, holding  $m$  constant, then the probability of actually completing  $x$  steps in an interval  $T$  is described by the Poisson distribution,

$$p(x) = e^{-m} m^x / x!$$

where  $x$  is a random variable because the steps vary in length or difficulty. The rapid decline in  $p(x)$  as  $x$  increases reflects the unlikelihood of "catching up" a delayed step by completing an additional step in a later interval.<sup>6</sup> The terms  $m^x/x!$  sum to  $e^m$  over all nonnegative values of  $x$ .

If  $m=1$ , so that the time appears to be just adequate, the project will in fact take 2.71828... times as long to complete as anticipated. What happens if the time available *ex ante* appears to be too short? If  $m=2$ , for

<sup>5</sup>So-called "interminable" jobs are the proper domain of Murphy's Law.

<sup>6</sup>A complete theory of personal stress reduction is built on this by Orff (1969).

example, the ratio of time taken to time expected becomes  $e^2$  or 7.3891...: trying to squeeze a project into half the required time makes it take not twice as long to finish as was anticipated, but nearly eight times as long. This explains Shaughnessy's (1937) finding that attempts to speed up projects by unrealistic deadlines actually end by slowing them down.<sup>7</sup> Letting  $C$  be the time taken to complete a project, the foregoing establishes

**THEOREM 2:**  $R = C/NT \rightarrow \exp(NT/A)$ , as  $N, A \rightarrow \infty$ ; for  $T$  constant.

It is a corollary of this theorem that a job can actually be completed in exactly the time expected—a result which Theorem 1 does not permit—but only on condition that it be expected to use a negligible fraction of the available time. The proof is direct:  $R=1$  requires  $\exp(NT/A)=1$ , from which  $NT/A=0$ . This result also accords with experience: the only jobs finished on time are those for which nobody is in a hurry.

<sup>7</sup>Shaughnessy's results for Soviet labor productivity are violently disputed by Vodkapiu (1937), who—curiously—published first. Subsequent evidence, however, tends to vindicate Shaughnessy.

# The Design of an Optimal Insurance Policy: Note

By GEORGE BLAZENKO\*

In an article in this *Review*, Arthur Raviv (1979) examines Pareto optimal insurance policies when an insurer incurs settlement costs  $C$  induced by indemnity " $I$ " for loss  $x$ . Raviv's main result is that a necessary and sufficient condition for the Pareto optimal deductible to equal zero is  $C'(I) = 0$ . This implies that deductible policies give the best tradeoff between risk sharing and economizing on costly claim settlements. Since in practice these costs are significant, the theorem is of considerable importance. Among others, this has been recognized by Robert Townsend (1979), Michael Brennan and Ray Solanki (1981), David Mayers and Clifford Smith (1981), Gur Huberman, Mayers, and Smith (1983), Harris Schlesinger (1981), and Stuart Turnbull (1983). The theorem is correct, but Raviv's proof is not.

In this note a corrected proof for the theorem is given. The corrected proof is important in itself because it allows for a generalization to a greater variety of transactions costs than has previously been considered (see my 1984 paper for details). Section I develops the setting for the problem and the notation to be subsequently used. Raviv's error and the corrected proof are presented in Section II.

## I. Insurance with Costly Claim Settlement

The insured faces a random loss  $x$ ,  $0 \leq x \leq T$ , with density  $f(x) > 0$ . Insurance indemnity is given by the schedule

$$(1) \quad 0 \leq I(x).$$

Costs of claim settlement are given by  $C[I(x)]$  with  $C' \geq 0$ . This cost represents a deadweight loss relative to both insurer and

insured. For simplicity, it is assumed that  $C[0] = 0$ .

The insurer's final wealth is  $W_0 + P - I(x) - C[I(x)]$ , where  $W_0$  is initial wealth and  $P$  is the premium. The insured's final wealth is  $\omega - P - x + I(x)$ , where  $\omega$  is the insured's initial wealth.

Twice differentiable utility functions for insurer and insured are  $V$  and  $U$ , respectively, both concave increasing. To find Pareto optimal contracts the insured's expected utility is maximized subject to the insurer reaching a required utility level.

$$(2) \quad \max_{P, I(\cdot)} \int_0^T U\{\omega - P - x + I(x)\} f(x) dx,$$

subject to (1) and

$$(3) \quad \int_0^T V\{W_0 + P - I(x) - C[I(x)]\} \times f(x) dx \geq K \geq V(W_0).$$

The Hamiltonian is

$$(4) \quad U\{\omega - P - x + I(x)\} f(x) + \lambda V\{W_0 + P - I(x) - C[I(x)]\} f(x),$$

where  $\lambda$  is a constant. Necessary conditions for a maximum with respect to indemnity are,

$$(5) \quad U'\{\omega - P - x\} - \lambda V'\{W_0 + P\} \times (1 + C'[0]) \leq 0 \quad I^* = 0,$$

$$(6) \quad U'\{\omega - P - x + I^*\} - \lambda V'\{W_0 + P - I^* - C[I^*]\} (1 + C'[I^*]) = 0 \quad I^* > 0.$$

Assuming the Hamiltonian is concave in  $I$ , necessary conditions are sufficient for a maximum. The relation,  $P(\bar{x})$ , between the de-

\*Accounting Group, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada.

ductible  $\bar{x}$  and the premium  $P$  is

$$(7) \quad U'\{\omega - P - \bar{x}\} - \lambda V'\{W_0 + P\}(1 + C'[0]) = 0.$$

Equation (6) implicitly defines  $I^*$  as a function of  $x$  and  $P$ , but since  $P$  is an implicit function of  $\bar{x}$  through (7),  $I^*$  can be considered a function of  $x$  and  $\bar{x}$ .

## II. Deductible Policies

Raviv's aim is to find  $\partial P / \partial \bar{x}$  given that the insured's expected utility is constant and  $\partial P / \partial \bar{x}$  given that the insurer's expected utility is constant, and show that the former is greater than the latter. If this is true, the reduction in premium the insured requires to maintain utility for an increase in deductible is less than the maximum premium reduction the insurer is willing to accept. In such a case it is possible to increase utilities of both by increasing the deductible. The implicit function theorem is used to find the derivatives. These depend upon the optimal indemnity schedule  $I^*$ , which in turn depends upon the loss and the deductible. However,  $I^*(x, \bar{x})$  and  $\partial I^*(x, \bar{x}) / \partial \bar{x} = \partial I^* / \partial P \cdot dP(\bar{x}) / d\bar{x}$ , which appear in the desired derivatives encompass equation (7) which determines the relation  $P(\bar{x})$ . This means that when writing insurer and insured expected utilities as functions of the indemnity schedule  $I^*(x, \bar{x})$  the relation  $P(\bar{x})$  between the premium and the deductible is assumed. To seek a further relationship between the premium and deductible holding expected utilities constant is inappropriate. Insurer and insured expected utilities based on the indemnity schedule  $I^*(x, \bar{x})$  must be treated as functions of  $\bar{x}$  alone, the premium  $P$  and the deductible  $\bar{x}$  are not free to vary independently.

### A. Corrected Proof

From (7)

$$(8) \quad dP/d\bar{x} = -R_u(\omega - P - \bar{x}) / [R_u(\omega - P - \bar{x}) + R_v(W_0 + P)] \leq 0,$$

where  $R_u$  and  $R_v$  are the Arrow-Pratt indices of risk aversion. The insured's expected utility with a deductible policy is

$$U^*(\bar{x}) = \int_0^{\bar{x}} U\{\omega - P(\bar{x}) - x\} f(x) dx + \int_{\bar{x}}^T U\{\omega - P(\bar{x}) - x + I^*(x, \bar{x})\} f(x) dx.$$

The derivative with respect to  $\bar{x}$  is

$$-P'(\bar{x}) \int_0^{\bar{x}} U'\{\omega - P(\bar{x}) - x\} f(x) dx + \int_{\bar{x}}^T U'\{\omega - P(\bar{x}) - x + I^*(x, \bar{x})\} \times [-P'(\bar{x}) + \partial I^* / \partial \bar{x}] f(x) dx.$$

The insurer's expected utility is

$$V^*(\bar{x}) = \int_0^{\bar{x}} V\{W_0 + P(\bar{x})\} f(x) dx + \int_{\bar{x}}^T V\{W_0 + P(\bar{x}) - I^*(x, \bar{x}) - C[I^*]\} f(x) dx.$$

The derivative with respect to the deductible is

$$V'\{W_0 + P(\bar{x})\} P'(\bar{x}) \int_0^{\bar{x}} f(x) dx + \int_{\bar{x}}^T V'\{W_0 + P(\bar{x}) - I^*(x, \bar{x}) - C[I^*]\} \times [P'(\bar{x}) - (1 + C') \partial I^* / \partial \bar{x}] f(x) dx.$$

Problem (2) is completed by maximizing

$$(9) \quad U^*(\bar{x}) + \lambda V^*(\bar{x})$$

with respect to  $\bar{x}$ ; this gives the Pareto optimal deductible. Constraint (3) serves to determine  $\lambda$ .

The derivative of (9) evaluated at  $\bar{x} = 0$  is

$$\begin{aligned} & -P' \int_0^T [U'\{\omega - P - x + I^*\} \\ & \quad - \lambda V'\{W_0 + P - I^* - C\}] f(x) dx \\ & + \int_0^T [U'\{\omega - P - x + I^*\} \\ & \quad - \lambda V'\{W_0 + P - I^* - C\} (1 + C')] \\ & \quad \times \partial I^* / \partial \bar{x} \cdot f(x) dx. \end{aligned}$$

From (6) the second term is zero. Also from (6), and assuming  $C' > 0$ , the first term in square brackets is positive. This means the entire first term is positive and therefore the Pareto optimal deductible is not zero. If  $C' = 0$ , both terms are zero and the Pareto optimal deductible is zero.

If (9) is maximized at  $\bar{x} = T$ , a risk-sharing arrangement that makes both parties better off is not possible. In this case the costs of claim settlement overwhelm the advantages of risk sharing.

# A Further Comment on Preemptive Patenting and the Persistence of Monopoly

By JONATHAN A. K. CAVE\*

Several recent papers in this *Review* have raised the question of whether the patent system can lead to inefficiencies in the innovative process by encouraging inefficient incumbent firms to preempt more efficient rivals. (See Richard Gilbert and David Newbery, 1982; 1984, and Stephen Salant, 1984.) In the course of this discussion, the focus has shifted away from the interesting question of whether innovation will be done efficiently to the tangential issue of whether an incumbent firm or a rival will do the innovation. I shall argue that any such inefficiency of innovation is limited by the possibility of bargaining, and that the issues of which markets are allowed to function and which party does the innovation, raised in the Reply by Gilbert and Newbery (1984) to the Comment by Salant, are somewhat beside the point.

Salant argued that the possibility of post-innovation bargaining between the incumbent and a more efficient entrant limits the profitability of inefficient preemption. Gilbert and Newbery point out that the incumbent may be able to purchase the *R&D* technology of the entrant at a price, which means that the incumbent will still develop the innovation. I wish to make two simple points. The first is that the transactions cost of purchasing an alternative *R&D* technology serves as an upper bound on the cost disadvantage of the incumbent firm, so its introduction reinforces Salant's contention that the adverse efficiency implications of the patent system are less than they appeared in Gilbert and Newbery's 1982 article. The second point is that the possible purchase of the efficient *R&D* technology by the incumbent limits the extent to which innovation by the incumbent merits the epithet "inefficient."

As I understand it, Salant's contention runs something like the following. An incumbent facing the possibility of a patent race has the following choice: he can wait for an entrant to win the race, and then strike a bargain with that entrant; or he can spend enough money to preempt the entrant, this being the amount the entrant spends plus the "disadvantage"  $\Delta$ .

Suppose that a successful entrant would earn an amount  $X$  from the bargain; competition among entrants will ensure that each serious contender is "bidding"  $X$ , so that the incumbent firm must spend at least  $X + \Delta$  to preempt. Assuming that monopoly profits are  $M$ , the value of preemption to the incumbent is

$$(1) \quad M - X - \Delta.$$

On the other hand, the bargain may not be costless. Let us assume that it costs  $T$  to consummate the bargain. Assuming that the result of the bargain is monopoly profits to the industry, the monopolist will get

$$(2) \quad M - X - T.$$

Salant's point is that *R&D* will be done by the inefficient incumbent iff the quantity in (1) exceeds the quantity in (2), or, equivalently, iff

$$(3) \quad T \geq \Delta,$$

which seems unsurprising. In other words, the opening of a costly market between the incumbent and the entrant places a bound on the inefficiency characterizing the innovative process. A firm with a large cost disadvantage would not choose to preempt; instead it would choose the more profitable path of waiting to see which entrant wins the race, and then striking a bargain with that entrant.

\*The Rand Corporation, 1700 Main Street, Santa Monica, CA 90406. I thank Robert Clower and an anonymous referee for editorial assistance.

In their Reply, Gilbert and Newbery differ heatedly with this conclusion. They point out that the market opened by Salant is just one of several markets whose closure or inefficient (costly) functioning is responsible for their result. They mention the bargain over the fruits of the patent race that Salant refers to, with the difference that the transactions cost  $T$  is renamed  $\Gamma_2$ . In addition, they mention another possibility: the incumbent could obviate his cost disadvantage by purchasing the superior  $R\&D$  technology that, in their model, is the sole reason for the entrants' cost advantage over the incumbent. This transaction has an associated transactions cost that Gilbert and Newbery denote  $\Gamma_1$ .

Before going further, I should mention that the source of this superior technology and the nature of the transactions cost  $\Gamma_1$  are important. If the incumbent does acquire the new technology and thereby wins the race, the innovation has at least been developed with the efficient technology. Therefore, preemption is not necessarily inefficient. On the other hand, unless the new technology is purchased from one of the most efficient entrants and  $\Gamma_1$  is a pure rent to that entrant, the cost to the industry of realizing the innovation is higher than it might otherwise have been.

Gilbert and Newbery allow for additional unmeasured imperfections in carrying out either of the bargains referred to, so that total industry profits from the post-innovation bargain between the incumbent and the successful entrant may be less than  $M - \Gamma_2$ . In addition, the incumbent who succeeds in beating an entrant spending  $X$  may spend more than  $X + \Gamma_1$ . However, the authors offer no explanation for these leakages, and I shall neglect them.

In any event, if the incumbent buys the new technology (for  $X + \Gamma_1$ ) and beats the entrant, he gets

$$(4) \quad M - X - \Gamma_1.$$

If the incumbent preempts the entrant using his old (inefficient)  $R\&D$  technology, he gets

$$(5) \quad M - X - \Delta.$$

On the other hand, if he loses and bargains with the entrant, he gets

$$(6) \quad M - X - \Gamma_2.$$

In this presentation, preemption will be worthwhile iff the transactions cost associated with bargaining over the patent exceeds either the transactions cost associated with purchasing the new  $R\&D$  technology or the incumbent's cost disadvantage:

$$(7) \quad \Gamma_2 \geq \min\{\Gamma_1, \Delta\}.$$

$\Gamma_2$  and  $T$  are manifestly identical; the substantive issue concerns the relation between  $\Gamma_1$  and  $\Delta$ .<sup>1</sup>

If (7) does not hold, the innovation will be developed (efficiently) by an entrant using the better  $R\&D$  technology. If (7) does hold, and if  $\Delta > \Gamma_1$ , the innovation will be developed by the incumbent, but the incumbent will be using the new technology. If the issue is the efficiency of innovation and not the question of who does the innovation, our attention shifts to the nature of the transactions cost  $\Gamma_1$ . To the extent that it represents a redistribution of profits within the industry, it does not affect the conclusion that innovation is still efficient. In any event, it places an upper bound on the inefficiency of innovation. Finally, if (7) holds, and  $\Delta \leq \Gamma_1$ , innovation will preempted by the inefficient incumbent.

Even if we take the position that the entire  $R\&D$  transactions cost  $\Gamma_1$  represents an inefficiency, we are left with the conclusion that the amount lost is limited. The introduction of the additional transaction has only served to weaken the argument against the patent system. On the other hand, the separation of this transactions cost from the incumbent's "cost disadvantage" requires some justification. As economists, we should

<sup>1</sup>In their Reply, Gilbert and Newbery focus on the "relative transactions costs" as a determinant of preemption. While I have argued that it is the cost disadvantage of the incumbent that must be compared to the transactions cost of bargaining over the patent, it seems quite implausible that the latter should exceed the cost of bargaining over the "pig in a poke" of a new  $R\&D$  technology.

be sufficiently comfortable with the concept of opportunity cost to recognize that in the absence of differential uncertainty about the outcome of innovative activity  $\Gamma_1$  is itself an upper bound on the cost disadvantage of the incumbent firm. After all, there are many ways of doing *R&D*, one of which is to purchase and use a new technology. A rational firm would certainly use the least expensive of these. This implies that  $\Gamma_1 \geq \Delta$ , and reduces equation (7) to Salant's equation (3). Thus, the transactions cost introduced by Gilbert and Newbery is irrelevant to the efficiency and preemption issues.

More importantly, while either  $\Gamma_1$  or  $\Delta$  may be relatively large, the meaning of (7) is that they will only result in efficiency losses if one of them is less than the transactions cost of patent transfer,  $\Gamma_2$ , which in reality is often fairly small.

All of the papers address themselves to the question of whether the possibility of preemption will lead to inefficient *R&D* expenditures. While it is difficult to discuss this sensibly in the context of a model that abstracts from demand and from the real resources consumed by unsuccessful competitors in a patent race, some lessons can be drawn. One of these, which I understood as being the point of Salant's Comment, is that the possibility of bargaining places an upper

bound on the inefficiency created by preemptive patenting. Gilbert and Newbery's Reply seems to miss this point entirely. The economically relevant issue is not whether preemption can occur, but whether the possibility of preemption has negative efficiency implications. In their attempt to deny Salant's contention that the possibilities for inefficient preemption are not as great as might appear in the absence of bargaining, Gilbert and Newbery inadvertently reinforce the implication that the inefficiency associated with innovation is bounded by the possibility of bargaining, regardless of who wins the patent race.

## A Curse on Several Houses

By BORIS P. PESEK\*

Suppose that the consumer has the choice among (a) a zero-yield and zero-risk asset, (b) a high-yield and excessively risky asset, (c) a low-yield and zero-risk asset, and (d) some real asset. If we restrict the consumer to the first two, he will select the first one, called "speculative balances." In our world in which the consumer has all four choices, he will never select these balances. One economist (see my 1976 paper) wasted almost two pages of the *Journal of Economic Literature* proving that a consumer will prefer a positive risk-free income to zero income. Three economists (Winston Chang, Daniel Hamberg, Junichi Hirata, 1983) wasted eight pages and some matrix algebra on a renewed effort to persuade the profession of the same thing. Linear extrapolation suggests that a renewed effort will become due in 1990.

But the problem is more serious. Given that the demand for speculative balances must be zero, Chang et al. ask (p. 46) why so many texts analyze the demand for them. I would add that these texts go on to raise the specter of a price-theoretic monstrosity—an infinite demand for speculative balances ("the liquidity trap") and its devastating consequences for monetary policy. This is not unusual. Texts give much space to the theory that current consumption is determined by unmeasurable future income, about which each of us forms only vague and changeable guesses (see my 1979 paper). The "Pigou effect" is "explained" to undergraduates even though its currency base (Don

Patinkin, 1969, p. 1154) is a microscopic fraction of national wealth, and even though the effect is theoretically superfluous (see my 1982 paper). Many other such cases could be mentioned.

Let me speculate why pedagogic failures litter our texts. The suppliers prefer to sell thick (expensive) books. Many of the intermediaries attract and impress students by endowing our field with more scientific content than it actually has. And, the captive demanders are not given protection by rigorous and extensive journal reviews of what should be the cornerstone of economics, the textbooks. Thus they are forced—to use Frank Knight's felicitous phrase—to "know too many things that just ain't so."

# Experimental Economics: Comment

By RONALD A. HEINER\*

In two important studies, Charles Plott (1982) and Vernon Smith (1982) assess the current state of the literature about laboratory experiments in economics. As a profession, we are becoming aware that experimental methods can be applied to our models, with cautious but growing confidence that these procedures can help us evaluate alternative theories. These are significant developments whose potential ramifications are only beginning to be explored.

Given the importance of laboratory testing, I would like to discuss a key feature of past experiments, one that has not been fully appreciated because of its central role in standard economic theory. In particular, these experiments depend on inducing agents to respond according to a prespecified value structure. This usually amounts to starting with a known and fully determinate set of demand and supply value schedules for all transacting agents. Smith, for example, specifies four major principles about how preferences are to be experimentally induced (non-satiation, saliency, dominance, and privacy; see pp. 931–35).

## I

I do not intend any criticism about induced preferences being somehow “artificial” or not “real.” Smith rightly points out that many naturally occurring or field markets also attempt to induce values by linking otherwise intangible assets (for example, airline travel vouchers) to specified bundles of rights to other more tangible commodities. Both field-induced and laboratory-induced preferences thus merit the same methodological status for theory evaluation. Plott also emphasizes that laboratory markets (although simpler and specialized compared to

natural markets) are still no less real than naturally occurring markets. They still represent legitimate special cases for which theories of general validity should be expected to apply.

The issue I raise is whether agents in non-experimental markets behave according to well-defined, complete preference orderings. What if agents must deal with uncertainty about which options are more or less preferred? Do natural or field markets simply reflect agent valuations that exist independently of exchange opportunities? Or do they help produce viable exchange patterns in the absence of fully determinate values of participating agents? Do markets simply combine pre-existing values, or do they organize a sequence of bids and offers as a feedback process helping agents cope with uncertainty in their own valuations?

Standard choice theory ignores these questions by postulating a complete preference ordering for each transactor. This applies whether preferences describe apple vs. orange consumption decisions, or an agent’s attitude toward risk between probabilistic contingencies. Yet, in each case, preference uncertainty is a plausible possibility.

For example, suppose we lined up before the customers of a grocery or department store a thousand randomly selected commodity baskets from the store. Is it likely that any of them would have secure beliefs about the relative value of all of the baskets? Moreover, if valuations for these commodity combinations are not well-defined, how it is that market prices are determined when there are no pre-existing value schedules to guide supply and demand decisions?<sup>1</sup> This does

\*Member 1984–85, The Institute for Advanced Study, Princeton, NJ 08540, and Brigham Young University.

<sup>1</sup>These issues are even more important for expected utility models of behavior under uncertainty, where agents can infer reliable probabilities of potential situations, or at least organize their experience into subjective probabilities of future contingencies. In addition, agents know all possible events that might eventuate, and all possible actions that might be useful to select. Such

not mean that agents' supply-demand behavior in field markets will fail to respond to price offers of other agents, or that a determinate market-clearing price will not be generated. Rather, the source of these regularities would have to be found in something other than agents reacting with no uncertainty about what is more preferred.

Preference uncertainty may also affect the convergence properties reported by Smith, and the efficiency measurements highlighted by Plott. The effect of changing exchange institutions or property rights may also depend on the type of uncertainty affecting agent valuations. Past experiments represent a special class of situations where agents have access to completely reliable value information to guide their interactions with each other.<sup>2</sup> But will convergence or efficiency properties be sensitive to the reliability of information that guides these interactions?<sup>3</sup>

Past experiments are also typically structured around an auction market process where agents follow specified rules to both make and respond to exchange offers of others. However, their success in dealing with each other may be significantly affected by how markets are organized, especially if agents are not guided by pre-existing valuations that are independent of how different kinds of markets generate price information.

Auction markets, for example, often produce a volatile sequence of price offers that agents must plan for and coordinate with

their individual consumption and investment decisions. Could this extra complexity contribute to uncertainty in agents' valuations, thereby conditioning where "flex" vs. "fix" price markets will evolve in an economic system? Could other features of intra- and intermarket organization (such as the evolution of money, firm organization, or ownership rules) indirectly result from how they affect agents' ability to cope with uncertain values?

The above queries about value uncertainty can be criticized in a number of ways. The simplest is to point out that these issues are outside the well-established theoretical purview of economics, which has always proceeded by postulating well-defined preferences for all transactors (whether they are commodity preferences, risk preferences, subjective probabilities, asset valuations, etc.). Past experiments are motivated within this theoretical context, and can be viewed as trying to determine the effects of this postulate for different institutional and property right settings.

Nevertheless, there is a crucial perspective from which questions of value uncertainty must be admitted, as suggested by a dominant theme of Smith's paper:

... The roots of our discipline require a complete reexamination; ... Above all, we need to develop a body of knowledge which clarifies the difference between what we have created (theory as hypothesis) and what we have discovered (hypothesis that, to date, is or is not falsified by observation). [p. 952]

---

ability to comprehend the future is much more difficult than avoiding computational mistakes in a world of known utility information over a fixed set of options (such as with a fixed product inventory from a store). See John Hey (1979, pp. 232–34; and 1981).

<sup>2</sup>This does *not* mean that these situations are irrelevant for testing. As emphasized by Plott, theories purporting general validity must therefore apply to special case laboratory environments.

<sup>3</sup>The idea of preferences as a potentially vulnerable information source is novel from the perspective of standard economic theory, and briefly discussed below in remark 3. For recent analysis about the viability of agents allowing their preferences to evolve rather than taking them as given, see Michael Cohen and Robert Axelrod (1984). See also Paul Slovic and Sarah Lichtenstein (1983, pp. 599–600, 602–03).

The assumption of well-defined preferences is the foundation from which our formal models are built; thereby representing the most important created element of our theoretical analysis. Thus, it is vital in the early stages of laboratory testing that we do not inadvertently establish a methodological precedent requiring future experiments to be structured around this created element. Rather, much in the spirit of these early experiments, we must broaden their design to investigate the effects of relaxing this created feature. For example, how are in-

dividual behavior and market structure affected by value uncertainty within different exchange situations?

A few brief remarks are directed toward this question:

1) How do we model the impact uncertainty on behavior, especially when agents cannot discern reliable probability information about the value of consequences resulting from their exchange commitments? Our formal models have almost universally ignored this issue.<sup>4</sup> I have elsewhere (1983, 1985) suggested a different theory in which genuine uncertainty, far from being unanalyzable, instead tends to produce regularity in behavior. The reason is that uncertainty requires an agent's flexibility to use information must be constrained to simpler behavior patterns that can be reliably administered. For example, a clear prediction of an inverse reaction to higher prices (i.e., the law of demand), is implied from preference uncertainty, which is not derivable if fully determinate preferences are assumed.<sup>5</sup>

2) Using uncertainty to regulate behavior has already been implicitly incorporated in the privacy condition discussed by Smith (see pp. 934-35). Maintaining privacy means agents are only informed of their own value schedules but not those of other agents. This condition makes interpersonal utility information highly uncertain, so that agents cannot reliably use such information to pursue interpersonal utility goals (i.e., they cannot reliably deviate from their pre-assigned value schedules). Consequently, agent behavior is simplified to patterns predicted from their individual value schedules, even though they might otherwise respond to interpersonal utility information.<sup>6</sup>

<sup>4</sup>Rational expectation theorists, such as Robert Lucas, even claim that *no* economic reasoning will be of value without well-defined, objective frequency information to guide behavior. See Lucas (1981, p. 224) and Steven Sheffrin (1983, p. 13).

<sup>5</sup>That is, the law of demand is implied without qualification for income effects as in standard Slutsky equation treatments. See my 1983 article, pp. 579-80.

<sup>6</sup>Similar results also apply to experiments reported by Plott that varied what agents were permitted to know about other agents. Plott states, for example, in the "incomplete information" experiments of Fouraker and Siegel, a simpler pattern of convergence around the

3) A recent example of experiments where induced preferences have an element of uncertainty is Plott and Shyam Sunder (1982). Each participant is assigned a value function that depends on realized dividend rates, which in turn depend on (two or three) states of nature (generated by a bingo device before each trading period starts). Such experiments are a legitimate but limited step to incorporating preference uncertainty. They are limited because: uncertainty is produced by a statistical process which is exogenous to the resulting trading interactions between participants; only two or three exogenous states of nature are involved; each state of nature produces the same type of mathematically prespecified change in agents' assigned value schedules (whose functional forms are also known and invariant to realized states of nature).

More basic features to address in experimental design are value uncertainties that cannot be resolved except through agents committing themselves to particular exchange offers as prompted by actual participation with other competing agents. A closely related question is how such uncertainty affects behavior within a given market when that market is itself embedded within several interconnected markets which differ in their internal organization. This may be a clue to why differently organized markets evolve into stable patterns of interdependence with each other.

4) In standard choice theory, preferences are the ultimate reference point from which agents evaluate their behavior. Thus, preferences are necessarily that which they should maximize. When values are uncertain, however, preferences do not necessarily have special status over other information that might affect behavior. Rather, they are simply another information source which may or may not reliably direct how to act.<sup>7</sup> An agent's

competitive equilibrium price was observed compared to that generated under "full information" conditions (see p. 1513).

<sup>7</sup>The same issue applies to any behavioral feedback process affected by an agent's perceptual mechanisms, such as expectations about future price or wage movements, asset yields, government policy, etc. See also the references cited in fn. 3 above.

preferences instead represent an internally generated feedback process that helps guide how to interact with the environment.

Exchange environments also enable agents to interact with each other in an organized and often repeated fashion. Markets thus provide agents with additional feedback that may help guide their behavior.

The objective now becomes to understand how different environmental settings (for example, different institutions or property rights) affect the reliability of individual and market guidance processes, thereby affecting the exchange patterns and market organization that will arise in these situations. In pursuing this objective, the analysis of feedback mechanisms studied in cybernetics may be a fruitful tool, one that has been little used in economics.<sup>8</sup>

## II

Laboratory experiments in economics have been structured around the assumption of fully determinate preference orderings, usually in the form of prespecified demand and supply value schedules. This assumption is basic to standard choice theory, but it is nevertheless a theoretically created rather than an empirically discovered feature.

Thus, if our objective in the development of laboratory testing and methodology is to distinguish between creation and discovery, a broadening of experimental design to allow for value uncertainty is necessary. In so doing, significant further discovery may be identified, especially in more complex exchange environments where the effects of

uncertainty will become increasingly important.

<sup>8</sup>As just one possibility, we can use information theory to measure the complexity of behavior necessary to fully maximize different preference relations (for an introductory discussion, see Ross Ashby, 1963, ch. 11). This required complexity (in order to maximize) may far exceed that which an agent can reliably administer (see my earlier paper, 1983), thus producing behavior which deviates substantially from that implied by standard optimizing models, or which may produce regularities in the way preferences evolve that are able to affect behavior.

## Experimental Economics: Comment

By DANIEL FRIEDMAN\*

In his comment on experimental methodology in this issue, Ronald Heiner reminds us that the evidence for a bedrock assumption of economic theory—the existence of well-defined individual preferences—is not very compelling in nonexperimental market settings. Of course, this point in itself is not new: it is a central theme in the first three books reviewed in the General Economic Theory section of the June 1983 issue of the *Journal of Economic Literature*, for example. Heiner goes on to suggest that the inducement of value itself be studied experimentally, and I agree that this is a potentially important area of research.

To a certain extent, “preference [or value] uncertainty” has already been incorporated in some laboratory experiments. For example, Charles Plott and Shyam Sunder (1982) and my paper with Glenn Harrison and Jon Salmon (1984) induced state-contingent preferences, the actual state being unknown during some trading periods. Well-defined *probabilities* over states were induced in these experiments however, and the results were surprisingly (to me at least) consistent with expected utility theory. It might be interesting to see what happens when such probabilities are *not* induced. For instance, subjects might be told that the state of nature has

already been determined in some unspecified manner, but will only be revealed after the market closes.

I suspect that Heiner would not be fully satisfied with such experiments. He raises the interesting possibility that individual preferences may *mutually* interact with the exchange process and market organization in nonexperimental settings. In particular, the standard assumption that preferences are independent of market activities may blind us to important phenomena. Experimentalists, I am sure, would welcome suggestions for laboratory tests of this possibility, and Heiner may find (as several other theorists already have found in different contexts) that his own alternative theory will be sharpened if he tries to devise such tests.

# Experimental Economics: Reply

By VERNON L. SMITH\*

More than in any particular method of inquiry, I think the hallmark of science is to be found in a constructively skeptical attitude toward knowledge.<sup>1</sup> The more funda-

\*Department of Economics, University of Arizona, Tucson, AZ 85721.

<sup>1</sup>The principal contribution of Popper's falsificationist methodology is, I believe, the influential attempt to develop a formal logic of skeptical inquiry. That the attempt has failed, in the sense that it has produced no defensible codified set of procedures that yield a science of scientific method (happily it would appear that all such attempts will fail), should not detract from the disciplinary value of the falsificationist perspective in approaching scientific questions. Its value to the experimentalist is to force him to ask "How can I design an experiment with the property that the set of potentially observable outcomes can be partitioned into those that are consistent with one (or a given) theory and those that are consistent with other theory(ies) (or inconsistent with the given theory)?" That experimental life is such that his effort is about as likely to fail as to succeed by no means detracts from the value of the exercise. Its value to the theorist (if he will just forgo the career-advancing primeval incentive to publish yet another technically tractable extension of the existing theory literature) is to force him to ask "How can I model this question so as to suggest (as Martin Shubik would say) a do-able experiment, and so as to yield observable implications that do not exhaust the set of possible outcomes?" That this effort will often fail does not detract from the value of the exercise. Having said this I would not want to leave the impression that experiments that are fishing expeditions in the laboratory to see what will happen are of no value; seeing what happens can be essential in defining an analytical-empirical research program. Similarly, when a theorist builds (as Buz Brock would say) castles in the air, this is not necessarily useless, for it may lead to more operational forms of theory. We should impute some non-zero probability to the proposition that Feyerabend's "anything goes" posture is right. But at this stage I think it has become pretty obvious where our professional weaknesses are concentrated. Economists, while spouting the rhetoric (Donald McClosky, 1983) of the falsificationist, are in fact verificationist to the core. We all do it. We take a proposition, conjecture, or theory, then search for supportive historical or empirical examples. As everyone ought to know, seek and ye are likely to find, whether one is a "Keynesian" or a "supply sider." What is not sufficiently appreciated is that this verificationist grubbing is a prescientific exercise in which one asks whether there is *any* supporting evidence, and

mental are the concepts and assumptions of a science, the easier it is to take them for granted and to abandon this skepticism. In this spirit, Ronald Heiner (1985) is correct in emphasizing that the "knowledge" obtained from the study of the performance of experimental markets is only as secure as the classical preference model used to induce prespecified value structures on the agents in such markets. If the purpose of an experiment is to test a theory (for example, supply and demand), and the theory is not "falsified" by the test, this in no way supports any premise of the theory which was also a premise of the experimental design. When we falsify a theory, the implication is that one or more of its assumptions about the behavior of economic agents (maximization of expected utility, commonly shared (homogeneous) expectations, risk aversion, zero subjective costs of transacting, etc.) is in question, and the immediate task is to modify the suspected behavioral assumptions of the original theory. Other assumptions—such as that agents have well-defined preferences, or know the probability distribution from which other agent values were drawn—are not brought into question by the experiment because the experimental design reproduced (or should have) the environment posited by the theory being tested. When testing formal market theories in this way, we should always be aware of the fact that *we are studying behavior within the context of our representations of the economic environment*. If any of these representations is wrong, then our studies have only increased our self-knowledge, not our knowledge of things (natural economic processes).

If we are to increase our knowledge of things, then our ultimate aim should aspire to more than discovering that the behavioral

---

how difficult it is to find; if there is none or if it is pretty hard to uncover, it suggests abandonment in the prescientific womb.

properties of our own creations are consistent with controlled experimental evidence, although the attempt to falsify these creations may be a necessary step in acquiring the conditional knowledge that can improve our theorizing ability. This is why empirical investigations of all aspects of parallelism between laboratory and field behavior are important. Similarly, our experimental and other investigations should not be *confined* to testing formal theory (for example, nomothetic experiments) since this objective requires us to impose more structure on the free play of decision making than ultimately may be justified. Finally, our research methodology should not be too rigid in testing only the market implications of a theory (or in testing only the assumptions of a theory).

Thus, John Kagel et al. (1981) have addressed direct tests of the observable implications of preference theory. This literature reports results consistent with standard preference theory (i.e., with Hicks-Slutsky income-compensated demand theory), but also with the *ad hoc* widely assumed law of demand, which Heiner (1983) is able to deduce from his model of adaptive uncertain choice.<sup>2</sup> As noted by Kagel et al., the convergence tendency reported in auction market experi-

ments "depends critically on the fact that subjects behave in a way which is consistent with utility-maximizing principles underlying consumer demand theory and that negatively sloped demand curves have been induced in the market" (p. 13). I do not wish to suggest that these studies have put to rest the issues raised by Heiner whose emphasis is on the inadequacy of standard theory when preferences are uncertain. Indeed, both the animal and especially the human preference studies of Kagel et al. exhibit "dynamic" effects or lagged responses that are not even supposed to exist in received preference theory, and which may reflect the "insecure preference beliefs" suggested by Heiner (1983). It would seem that lagged responses are inconsistent with a cognitive, calculating interpretation of preference theory, but consistent with some sort of adaptive response interpretation. Even if preference theory accounts for many agents' stationary state choices in certain experimental situations, it tells us nothing about the *processes* that yield these "good" predictions or why some agents' behavior is not consistent with the theory. The failure of animal studies to falsify demand theory can be interpreted as lending support to Heiner's (1983) emphasis on rule-governed behavior although here the "rules" are apparently programmed into the instincts (genes), unless we are prepared to accept the proposition that species other than ours have cognitive decision-making powers.

Furthermore, the numerous direct studies of individual decision making under uncertainty, over the past 25 years (see the recent papers by David Grether, 1980; Grether and Charles Plott, 1979; and especially the survey and evaluation by Paul Slovic and Sarah Lichtenstein, 1983), suggest that our theories of decision under uncertainty are in several respects inconsistent with controlled evidence. The results of these experiments are robust under replication, and various artifactual explanations of the results (that might have rescued the theory) have been systematically eliminated. The results are not to be idly dismissed by anyone with the slightest interest in evidence. What I want to suggest is that (so far as we are able to tell) experimental methods are entirely competent

<sup>2</sup>Since it seems that no one has ever produced any rigorous evidence for the existence of a price inferior good (Sir Giffen was just speculating, and had no controls on his "experiment"), its prediction by textbook theory is a curiosity (which was recognized as such by Alfred Marshall who started it all), that should have counted against the theory, just as the failure to find a planet "Vulcan" between Mercury and the sun (there was no shortage of claimed sightings), that would account for the advance of Mercury's perihelion, ultimately counted against Newtonian theory (David DeVorkin, 1983, p. 1058). In more mature sciences this might have sparked analytical interest in producing a theory consistent with the law of demand, but having other falsifiable implications. Contrarily, in economics such a theory might even be considered unpublishable because of its "lack of generality," and the Giffen good curiosity has sparked an endless preoccupation with examples of "multiple" and "unstable" equilibria based on the Walrasian adjustment mechanism, which is itself devoid of any institutional evidence. These have been good analytical exercises, but so far as I can see all this self-knowledge is good only for teaching the defenseless and uninitiated students who will form the next generation of automata.

to examine these important issues. New theory, such as that proposed by Heiner (1983) and Soo Hong Chew (1983) (also see Don Coursey, 1982) are particularly welcome at this stage in research programs using, or directly concerned with testing, preference theory under uncertainty.

However, among those who take these experimental results as a serious challenge to existing theory, not all may interpret them in the same way. In the following I will try to state some of my interpretations, and relate them, where it seems appropriate, to Heiner's work.

1) The state of experimental research on decision under uncertainty has produced many unresolved anomalies. Experimental tests of *market* theories, which explicitly assume expected utility (or value) maximization, have *not* falsified many of these theories (for example, James Cox, Bruce Roberston and myself, 1982; Plott and Louis Wilde, 1982). Yet, as indicated above, the results of direct tests are inconsistent with the expected utility hypothesis (*EUH*). Some, but not all (for example, violation of simple dominance), of these anomalies are resolved by Chew's weighted expected utility hypothesis (*WEUH*). Although at this stage I think it would be premature to abandon *EUH*, and especially its extensions, it is not premature to work on the resolution of these anomalies. (One did not reject Newton's inverse square law of attraction because the planets failed to move in perfect ellipses, nor because of the highly inconsistent observed advance in the perihelion of Mercury.)

2) One route to such a resolution may be to recognize, and to elaborate more formally, the hypothesis that subjects are more rational (in the sense of received decision theory under uncertainty) in the context of laboratory markets, than when responding to questionnaire choices among prospects, because of Heiner's conjecture that "Exchange environments also enable agents to interact with each other in an organized and often repeated fashion. Markets thus provide agents with additional feedback that may help guide their behavior" (1985, p. 263). From the study of experimental markets, I have long thought that markets may induce

greater "rationality" in behavior because they force or promote a response to, or discovery of, opportunity cost conditions, that need not be readily forthcoming when agents merely think about the choices they make. What I have in mind may be close to Armen Alchian's (1977, pp. 27-32) imitative and trial-and-error forms of conscious adaptive behavior, except that I would deemphasize the "conscious" element.<sup>3</sup>

Different forms of market organization have been found to differ in their power to induce or extract neoclassical rational behavior. Thus the English auction is slightly more efficient (97 percent of the allocations are Pareto optimal), and prices are consistently closer to the predicted second highest value among the bidders, than is the Second price sealed-bid auction (94 percent Pareto optimal allocations) (see Cox, Mark Isaac, and myself, 1983, pp. 73-75). An explanation is simple. In the English auction it is a dominant strategy to raise the standing bid if it is less than your value, and to never raise your own bid. Behaviorally, the temptation to use this strategy is irresistible, and made transparent (without thinking) by the sequential complete bid information properties of the process. In terms of Heiner's model (1983), subjects easily (I would say at low cost)

<sup>3</sup> In writing this reply, I found myself reminiscing that Adam Smith did not begin his economic analysis, as does mainstream economics, with preferences as the primeval cause of the phenomena we study. He began with a deeply insightful *observation qua axiom*, which states that man is unique among all animal species in exhibiting "the propensity to truck, barter and exchange one thing for another." (Man is not unique in revealing preferences.) After some speculation that this might be a consequence of man's ability to use language (I would speculate that man's development of language may have been in part due to the specialization and affluence made possible by markets), Smith deduced the important result that it is this power of exchanging that gives rise to wealth creating specialization, which in turn is limited by the extent of the market. Markets thus lead agents to promote ends which are no part of their intention. Except for modern scholars such as Hayek, the idea that we are studying processes that contain major elements that are *not* consciously or cognitively purposive has been lost in the pyrotechnics of straightening out Smith's little paradoxes of value. No wonder that Kenneth Boulding will tell you flat out that Smith was the first great post-Newtonian scientist.

perceive, perhaps quite unconsciously, the opportunity cost of "nonoptimal" behavior. In the Second price sealed-bid auction it is a dominant strategy to submit a bid equal to your value. But this requires *reasoning* which is in fact *very subtle*, although, as with all puzzles, it is obvious or "trivial" once you understand it.<sup>4</sup> One must perceive that if one's own bid is the highest, the price paid is the amount of the next highest bid, and therefore one's surplus to be gained is independent of the amount bid. So the "rational" bid is to maximize your chance of winning by bidding your value. About a third of the subjects recruited out of campus classrooms to participate in a sequence of Second price auctions (with values assigned independently from a distribution to all bidders in each auction), bid "as if" they perceive the implied dominant strategy from the beginning. About one-third appear to "learn" asymptotically from their success-failure experience that this is the "best" strategy. Another third do not clearly converge to the dominant strategy—some hit it irrationally, some rarely, if ever, and some bid just below value. An examination of the bids that are less than value reveals that many occur at values so low that the prospect of having the winning bid is remote. These can be interpreted as "throw-away" bids, and if in the strict sense they are "irrational," at least they are only marginally so.<sup>5</sup>

<sup>4</sup>Richard Thaler once reported in a seminar that, informally, he had gone around polling economists as to how they would bid, after describing the Second price auction procedure. This was before William Vickrey's discussion of this auction had become so well-known. He reported that very few got it "right." Most thought one should bid at least a "little" under value. The early polling of economists on Allais, Ellsberg, Second price, and other such "paradoxes" makes it clear that economists will get it "wrong" about as often as the sophomore subject (who of course we pay a monetary reward) until he or she has had considerable time to think and analyze. Incidentally, this observation provides an answer for that somewhat mythical businessman who asks, "If you're so smart why ain't you rich?" My classmate, Otto Eckstein, didn't get rich by equating price to marginal cost.

<sup>5</sup>An outstanding young economist once asked me why I was bothering to do Second price sealed-bid auction experiments since the dominant strategy property was so trivial. I encounter statements in this spirit

3) The wide variety of different experimental studies of decision making under uncertainty, yielding results inconsistent with *EUH*, are subject to different interpretations in terms of the damage they inflict on *EUH*. I think a key element in these interpretations is what Jacob Marschak (1968) long ago called the cost of thinking, calculating, deciding, and acting, which are all part of what I have called the subjective cost of transacting (*SCT*) (see my 1982 article, p. 934 and *passim*). Of course, one could argue that *EUH* and its Chew-Machina-type extensions are on the face of it inadequate theories because they leave *SCT* out of the formal apparatus. But this is much too harsh. Considerations of *SCT* are hard to formalize within a framework as general as that attempted in *EUH* and *WEUH*, that allow the latter to be deduced as limiting cases when *SCT* goes to zero, or when outcome values get large relative to a fixed *SCT*. But the modification of standard *EUH* theory by introducing *SCT* elements in particular decision-making contexts (Sydney Siegel, 1961), or in illustrative examples (my 1982 article, p. 934), point to the untapped potential of imbedding standard theories in larger (and more "rational") frameworks. How important are the *SCT* elements in the various decision contexts which yield violations of *EUH*?

(a) I think the class of violations which are due to Kahneman-Tversky framing effects (see Slovic and Lichtenstein, and the references therein), do relatively low level damage to *EUH*. The typical case here is that the options are identical in two situations except that in one the outcomes are stated in terms of what will be lost (deaths), the other in terms of what will be gained (lives saved). It seems to me that these are like elementary optimal illusions, which the individual, at comparatively low cost, can learn to recog-

---

so regularly that it has become a permanent way of life. They reveal two things: 1) how quickly, easily and matter of factly as economists we are prepared to believe our own propaganda (theorems), and to use these beliefs to insulate ourselves from evidence; and 2) how the use of experimental methods leads one to think about the world of economic knowledge in a fundamentally different way.

nize as such (for example, the individual can be taught that the death rate is one minus the survival rate. If it is hard to teach this, as it may be, then I am wrong in interpreting it as a low-cost recognition problem). We all learn that when the sun is low, the pond in the highway ahead is just a reflection, and we do not risk a rear-end collision by jamming on the brakes. In saying this, I do *not* mean to suggest that the study of framing effects is of no interest. On the contrary, these examples show how bad we can be at intuitive problem solving, and why it is important to examine a decision from alternative perspectives. Also, these examples vary in transparency. I find the second example cited by Slovic and Lichtenstein (p. 597) to involve more *SCT* than the first. I think the equivalence of the two situations in the first example could be conveyed to the uninitiated much more easily than the second. So some of these "optical" illusions may be more costly to expose than others.<sup>6</sup> Note that this *SCT* interpretation blurs the distinction often made between positive and normative economic theory, but I have never been convinced that such a distinction was very helpful.

(b) The preference reversal examples may represent still more sophisticated "opti-

cal" illusions, and may require rather more *SCT* to yield consistency of choice. However, the fact that they seem to be moderated (although they do not disappear) when the motivation is increased (Werner Pommerhne et al., 1982) is consistent with the hypothesis that subjects do seek to increase benefits net of *SCT*, even where the latter are relatively large. A preference reverser is of course vulnerable to a con game (money pump) in which a sequence of decisions will produce a loss in assets. Will a person discover his decision inconsistencies and learn the appropriate corrections in a money pump sequence? In this context *EUH* is being tested in a more market-like framework. J. E. Berg et al. (1984) report results showing that although the frequency of preference reversals is *not* reduced, the total value (dollar magnitude) of preference reversals is reduced. Apparently, there is positive interaction between the stakes, and the money pump treatment. They also report that the preference reversal phenomena tends to decline across experiments with the same subjects.

4) The results of direct laboratory tests of *EUH* have been used to explain the apparent failure of *EUH* in insurance, securities and futures markets (see Kenneth Arrow, 1982; Heiner, 1983). Although this appears to be evidence of parallelism in behavior between laboratory and field, I think we have to be particularly careful in drawing this parallel. There is first a question of the comparability of the quality of the evidence in the two environments, and second a question of whether *EUH* is failing for the same reason in the two environments. In the laboratory experiments, the situations are carefully controlled and structured, the states of nature are well-defined, and so are the outcomes. Consequently, the results are much more clearly interpretable as inconsistent with *EUH*, even if the cause of the inconsistency is an inappropriate carryover to the laboratory of Heiner's rule-governed agent whose habits have been developed in the more unstructured uncertainty environments of the field; or if, as I have suggested, the results can be interpreted in terms of *SCT*, and *EUH* is considered to be just a limiting case of a more general economic problem.

<sup>6</sup>In studies of science learning it is found that both weak and strong learners come to their first science classes with extensive "naive" theories about how the world works. They use these naive theories to explain physical events and tend, even after instruction in the new concepts and the scientific support for them, to resort to their prior theories to solve problems that differ from the textbook examples (Lauren Resnik, 1983). Of course with *EUH* we have the difficult problem of deciding when the subject is making a "mistake" (an "optical" illusion) which she can at more-or-less cost recognize as such, and when the theory is a mistake, or not relevant to the actual problem faced by the subject (which, for example, might be better represented by *WEUH* than *EUH*). The fact that about one-third of the subjects in sequential Second price sealed-bid auctions "learn" to make dominant strategy choices has been interpreted as analogous to learning that a certain mirage is an optimal illusion and the self-interest is not served by taking such a phenomenon at its face value (Vicki Coppinger et al., 1980, p. 20). Also see Thaler (1983) for a discussion of cognitive illusions and mirages in decision making.

An example may help to clarify one type of ambiguity in interpreting field observations in terms of *EUH*. Suppose you have had a sore rib for many weeks that hasn't healed. Your doctor sends you to the lab for an x-ray to "see if it is fractured." It is not fractured, and she tells you, "Well, a hairline fracture might not show, but it doesn't much matter since the treatment is the same whether it is a fracture or a contusion." You think, "This violates the Savage axioms!" Does it? How do you (or does she) know that there are only two states of nature, rib fractured or rib bruised, given that it is sore? Could a carcinoma behind the rib make it sore? There may be hundreds of causes of sore ribs, and it may not be worth anyone's trouble to list them all, or even to invest time in thinking about any significant fraction of them. A host of past experiences may have programmed your doctor to acquire information that appears to be redundant in this particular case, and she may be unable to organize these experiences into an articulate case for her actions because such a detailed cognitive treatment of every decision is neither a necessary nor a desirable feature of her *modus operandi*.

As a second example, take the reported reluctance of people to insure against rare disasters even though, since 1969, the government has offered subsidized flood insurance rates that are *below* actuarial value. Is it a fact that this violates *EUH*? If it is a fact, then I like Heiner's explanation that there is a tradeoff between the greater setup costs (these are part of what I call *SCT*) of insuring against more events of small probability, and the expected loss from failing to insure, and it is hardly economical to insure against everything. Hence, in the field situation *EUH* is failing because it formulates the *wrong economic choice problem*, by leaving out *SCT*. But it is not clear from the evidence that this is an example of the violation of *EUH*. Arrow tells us that the reason the government offered the subsidized insurance "was to relieve the pressure for the government to offer relief when floods occurred" (p. 2). If I have built a house on a flood plane, if flood planes sometimes flood (we call them 100-year floods in Arizona), and if

it is standard political procedure for the governor to declare it a disaster area, and the federal government to respond with relief when a flood occurs, then I might not buy insurance even at rates below actuarial value. (This need not be a conscious decision with people able to state that the failure to buy insurance was due to the expectation of government relief.) Without better controls on the experimental treatment variable, I don't know how to interpret the observations. This problem does not reflect on the quality of these excellent studies cited by Arrow, but on the difficulty of doing field experiments with the most desirable controls. Similar considerations apply when asking whether interest rates or stock prices vary "too much" (see the studies by Cagan and Shiller cited in Arrow). It is unclear what is to be concluded when the falsifying "facts" are no more than "an impression which many students of these markets and practitioners in them seem to have" (Arrow, p. 4).

But Stewart's finding that unprofessional speculators lose money in grain futures is cited by Arrow as "especially surprising," and he asks "why did they enter the market at all?" (p. 3). I would suggest that they do it for the same reason that people go to Las Vegas to play roulette, buy tickets in the Arizona Lottery, and play bingo at the local church on Thursdays. I don't see any way to understand these phenomena with *EUH* (it is well known that convex, risk-prefering, utility doesn't explain repetitive small stakes wagering) nor any way to understand them with Heiner's theory. I find it necessary, if not entirely satisfactory in terms of seeking a universal theory, to accept the idea that some people just simply like to gamble (ancient hunter cultures did it) and that it has commodity value, or perhaps that some people have "pathological" expectations, whether it is roulette, grain futures or stock investment. (See my 1971 article.)<sup>7</sup>

<sup>7</sup>If in all markets with uncertainty there is a subclass of participants with these "irrational" characteristics, this lowers the insurance cost of hedging and lowers the cost of capital to firms. The gamblers lose money volun-

I have no disagreement with Heiner's critique of classical preference theory, which is among the roots that should be reexamined. However, I would register disagreement with Heiner's interpretation of "privacy" as an experimental condition. As noted in my article (1982, p. 933, fn. 13; p. 935) the purpose of privacy is to maintain control over preferences. Privacy does not deny the existence of interpersonal externalities. The latter is achieved under controlled conditions by simply inducing the appropriate interdependent preferences if that is the topic of investigation. If one wishes to study the effect of "utility information" on behavior, one publicizes information on commodity allocations, or token earnings (which is analogous to income in the field), but not subject cash payoffs since these are to induce utility on allocations and indirectly on token income. The idea is to preserve the natural uncertainty about other's subjective value of allocations, and of the exchange medium.

tarily, the economy benefits and perhaps only *EUH* suffers as a predictive theory for some types of agents. But the existence of such agents in futures, stock, and option markets will cause such markets to appear to be irrational by our definitions, whereas actually these markets may be performing with high allocative efficiency, given the environment, by taking wealth away from the gamblers and giving it to the hedgers, investors, and rational expectationists. Isn't Las Vegas an exchange market between gamblers (customers) and rational expectationists (casinos)? The question may be not "Why are certain markets inefficient?" but "What is wrong with our interpretation of markets?" An important technical difference between casinos and financial markets is that in the former the agent learns immediately the outcome of her investment. But the more variable are the prices of financial instruments, the more will they have this casino characteristic, and the more attractive they will be to this type of investor. Hence, the alleged "fact" that security prices vary "too much" may be both the effect and the cause of its appeal to these kinds of investors.

I suspect that Adam Smith would wonder why there is so much modern professional interest in the internal efficiency or "perfection" of particular markets, and so little interest in what determines the extent of markets, and how this in turn may create social gains that are more important and significant than the "imperfections" in particular markets that are suggested by our theory of "rational" preferences.

# Relative Prices, Concentration, And Money Growth: Comment

By DANIEL J. RICHARDS\*

In a recent article in this *Review* (1983), Henry Chappell and John Addison provide new evidence on the "administered"-pricing thesis that links an industry's price behavior over the business cycle to its structural features, most notably, some measure(s) of the monopoly power possessed by firms in that industry. The approach taken by Chappell and Addison (C-A) is both sensible and novel. Essentially, they regress aggregate inflation measures for different groups of manufacturing industries on a distributed lag in monetary growth. The industry groups are distinguished by their degree of concentration—low, medium, or high—and the validity of the administered-pricing thesis is then tested by comparing the time pattern of response in each group to monetary impulses. Chappell-Addison conclude that this test reveals no clear response differences between the sectors of varying concentration, and hence reject the hypothesis of concentration-related administered prices.

The purpose of this comment is to show that the C-A conclusions are overly strong. Their focus on the mean lag as the sole basis of interindustry comparisons obscures important differences in the pricing performance of the low- and high-concentrated sectors. More fundamentally, the C-A test is misspecified in that it fails to differentiate between the expected and unexpected components of money growth as suggested by Robert Barro (1977). When the analysis allows for these modifications, the C-A data reveal considerable support for the administered-pricing hypothesis.

## I. The Chappell-Addison Model

A basic prediction of the administered-pricing thesis is that prices in concentrated industries will be less responsive to demand forces than prices in more competitive sectors (Adolph Berle and Gardiner Means, 1967). Chappell-Addison test this prediction by postulating the following model of inflation for any industry or group of industries:

$$(1) \quad \dot{P}_t = a_0 + \sum_{i=1}^k a_i \cdot \dot{M}_{t-i} + e_t;$$

where  $k$  = lag length,  $\dot{P}_t$  is the estimated rate of inflation, and  $\dot{M}_t$  is the rate of monetary growth in period  $t$ , respectively.  $\dot{M}_t$  is thus the principal measure of demand pressures. The monetary aggregate used to calculate  $\dot{M}_t$  is  $M_2$ . To compute inflation rates, C-A categorize all four-digit manufacturing industries into three groups according to "the industry's four-firm concentration ratio ( $CR_4$ ) as follows: high concentration  $CR_4 > 70$ ; medium concentration  $40 < CR_4 \leq 70$ ; and low concentration  $CR_4 \leq 40$ " (p. 1124). They then construct aggregate price indices and inflation rates for each group.

Equation (1) is estimated for each of the three groups using annual time-series data for the years 1959 through 1976. Ten different specifications are used, eight of which are based on the Almon lag technique, and two of which rely on ordinary least squares (*OLS*). The administered-pricing thesis is interpreted as implying a slower response of inflation to monetary growth as concentration increases, and the estimated mean lag is used as the measure of response speed. Chappell-Addison find that regardless of specification, there is little difference in the mean lag of the different industry groups. They therefore conclude that the results do not provide much support for a theory linking "sticky" or administered prices to increasing concentration.

\*Department of Economics, Hamilton College, Clinton, NY 13323. I thank Henry Chappell and John Addison who very kindly shared their data with me and provided helpful remarks on this research. I am also grateful for useful discussions with Jeffrey Pliskin, and for comments by Derek Jones and Elizabeth Jensen on an earlier draft.

## II. Is the Mean Lag the Appropriate Basis for Interindustry Comparison?

The C-A findings raise some difficult statistical issues, most of which relate to the mean lag as the basis of comparing inter-industry price responsiveness. The major difficulty with this procedure is that it confuses the size of a response with its speed. This is because the mean lag is calculated as a weighted average of the lag terms, holding the total effect constant. Given the sum of the estimated lag coefficients, the mean lag provides information about the time distribution of the overall impact this sum implies.

Summary statistics are often helpful and in this respect the mean lag is probably no worse than many others. For the purposes of Chappell-Addison, however, the fact that the mean lag comparisons contrast the time distribution of given total effects, without comparing the size of those total effects, is a crucial failure. To take an extreme example, suppose that they had found that the estimated coefficients on lagged money growth exactly doubled as one moved from the high-concentrated sector to the medium-concentrated sector, and doubled again as one moved from that sector to the low-concentrated sector. In this case, the mean lag would be precisely the same for each group. Yet the response of inflation to money growth after one, two, or several periods would be four times as great in the low-concentrated sectors as in the high-concentrated sectors. Thus, if by speed of response we mean the amount of movement that occurs per unit of time, the mean lag may clearly suppress important information.<sup>1</sup> Such ambiguity casts serious doubt on the utility of the mean lag as the sole basis of interindustry comparisons of price responsiveness. Moreover, in the case of the C-A estimates, this problem is greatly complicated by the fact that in virtually every one of their regressions, the coefficients (either explicit or implicit) on past money growth are of both positive and nega-

<sup>a</sup>Sum of the lag coefficients.

tive signs. In such cases, the very meaning of the mean lag statistic comes into question because the sign of an effect and the speed of an effect are far from the same thing.<sup>2</sup>

In light of the foregoing difficulties with the mean lag statistic, I have reviewed the C-A results and constructed some alternative measures of price responsiveness for the different industries. These are displayed in Table 1, and show for each industry the average effect of money on inflation after one or two years, and in the long run (the sum of the lag coefficients) that is implied by the C-A estimates. Attention to the one- and two-year impacts is motivated by the fact that the concern over administered prices stems largely from the debate over the ability of monetary deceleration to slow inflation quickly without imposing intolerable political costs. Given the frequency of elections, one or two years seems a reasonable time to allow for the effect of money on prices. To the extent it takes longer than this, the mone-

<sup>1</sup>This confusion could occur even when the sum of the lags is identical between sectors. Thus, in the C-A regressions, the lag structures 2 2 5 1 and 3 3 0 4 have exactly the same mean lag and lag sums.

<sup>2</sup>In personal correspondence, C-A have suggested that these difficulties could be solved by using the median lag statistic. If anything, I think this statistic would be inferior to the mean lag. In making interindustry comparisons, it suffers from the same problems as the mean lag in that it obscures important information. Moreover, in the presence of oppositely signed coefficients, the median lag is a particularly *ad hoc* number. It measures the earliest time at which half the ultimate effect is felt. But, why pick this shortest time interval? With oppositely signed coefficients there will be many points at which half the effect has occurred. To exclusively focus on the earliest of these seems highly arbitrary.

tary cure for inflation may not be politically feasible.

One clear pattern emerges from Table 1. The inflationary impact of monetary growth after one, two, or even several years is substantially less in the most highly concentrated industries than in the other two sectors. After one year, monetary deceleration would decrease inflation in those industries where  $CR4$  is below 70 percent by about three times as much as in those industries where  $CR4$  exceeds this level. After two years, the difference in impact declines a bit, yet the effect of monetary deceleration is still more than twice as great in the less-concentrated groups. Even in the long run, inflation in the highly concentrated sectors appears somewhat less responsive to monetary impulses, though the difference is much less in this case than for the one- and two-year effects. With respect to the price sensitivity of the sectors of low and medium concentration, any differences are less clear. Thus, increasing concentration does not appear to have much effect in the range of  $0 < CR4 \leq 70$ . But the results clearly indicate that raising concentration above this threshold level, does make prices more sticky.<sup>3</sup> As noted, these results are based on coefficient averages over a variety of specifications. But the same coefficient pattern appears in virtually each of the individual C-A regressions.<sup>4</sup>

Table 1 also shows the adjusted  $R^2$ s C-A obtained for each industry, again averaged over the different specifications. Note that these decline systematically as the level of

Source: C-A data.

concentration increases, a pattern that is again repeated in the individual regressions. (Similarly, regression standard errors increase with  $CR4$ .) There are many reasons why this might occur. But one obvious suggestion is that prices in more concentrated industries are influenced by many factors other than nominal money growth, and hence, move quite independently of that growth relative to prices in more competitive sectors.

It should be added that these findings are not substantially changed when the regressions are constrained so as to preserve money neutrality. Table 2 shows the results of reestimating the *OLS* equations when the sum of the coefficients on money growth are constrained to sum to unity. These results run parallel to the more aggregate measures shown in Table 1, and are especially similar to the unconstrained *OLS* estimates.

In short, the C-A focus on the mean lag obscures some important differences in inter-industry pricing behavior. When attention is given to the effect of monetary stimulus on prices over any particular time interval, the C-A estimates do in fact suggest considerable support for the administered-pricing thesis, at least at the highest level of concentration. Corroborating evidence for this view is provided by the  $\bar{R}^2$ s for each industrial group which suggest that the highly concentrated sectors set prices in response to a variety of nonmonetary factors not considered by firms in the less-concentrated industries. However, as the next section shows, the C-A conclusions would be open to question even without these ambiguities due to a serious flaw in their analytical framework.

<sup>3</sup> Chappell-Addison did not present any statistical tests of their mean lag comparisons. Similarly, in the results shown both here and in Table 2, I have also omitted statistical tests of differences in the coefficients of each equation. The simple fact is that the number of observations is small enough, and the problem of multicollinearity large enough, that none of the implicit coefficients on  $M_{t-i}$  are significantly different from 0. Nor do the interequation differences shown here pass the normal tests of statistical significance. Nevertheless, these differences seem both clear and highly instructive.

<sup>4</sup> It is true, of course, that over any particular time period, relative prices will change between the various sectors. But these differences in the sample-specific inflation rates should be accounted for by differences in the intercept term, not in the lag coefficients.

### III. An Alternative Specification Based on the Distinction Between Expected and Unexpected Monetary Growth

Unlike Barro, Chappell-Addison do not distinguish between unanticipated and anticipated money growth. Yet this distinction is crucial to their test of the administered-pricing thesis. Rational firms may be assumed to set their nominal prices at expected profit-maximizing levels. Under a wide class of models, especially those in the spirit of equation (1), these expectations will in turn depend on anticipated monetary expansion. If this is the case, and if anticipated money growth is the primary factor in total money growth, then using the latter variable to explain the industry's chosen path of price increases greatly confuses the issue. All firms and all sectors may exhibit similar responses to total money growth, simply because they are all reacting to the same, dominant, expected portion of that growth. In the context of the administered-pricing thesis, the real issue hinges on differences in the various sectors' separate responses to the anticipated and unanticipated components of monetary growth.

To this end, I have estimated regressions of the following general form for each of the three sectors studied by C-A:

$$(2) \quad \dot{P}_t = c_0 + \sum_{j=1}^k c_j(\dot{EM})_{t-j} + \sum_{j=1}^k d_j(\dot{UM})_{t-j} + u_t,$$

where  $\dot{EM}$  and  $\dot{UM}$  are expected and unexpected money growth, respectively. These were estimated by regressing actual  $M2$  growth on exactly the same variables as used by Barro over the years 1941 through 1976: the one-and two-period lagged money growth rates, a measure of "normal" federal expenditures, and an unemployment variable. The observations for  $\dot{EM}$  are the fitted val-

ues from this equation, and those for  $\dot{UM}$  are the residuals.<sup>5</sup>

The now relevant version of the administered-pricing thesis may be stated as follows. Inflation in the concentrated sectors will be relatively more responsive to expected money growth and less responsive to unexpected money growth than it will be in the less concentrated sectors. Competitive firms will respond to all market factors that affect the equilibrium price level. These include both  $\dot{EM}$  and  $\dot{UM}$ . Firms with monopoly power, however, will gear their pricing to  $\dot{EM}$ , and be reluctant to change their prices in response to unanticipated monetary shocks.  $\dot{EM}$  acts as a focal point about which oligopolistic competitors may easily coordinate their prices. By contrast,  $\dot{UM}$  represents the unforeseen "noise" to which oligopolists will be reluctant to respond out of the fear that this would generate too much price variability and hence reduce their ability to communicate with rivals through price signaling (Carliss Baldwin, 1983). Indeed, since all firms are assumed to have equal values of  $\dot{EM}$ , and assuming that expected money growth is neutral, the real differences between firms of varying market power should mainly lie in their response to  $\dot{UM}$ .

Table 3 parallels Table 1 and presents some summary statistics derived from estimating equation (2) with four different Almon lag specifications and two *OLS* specifications. In each of the Almon lag regressions, the polynomial degree and lag structure are specified to be the same for both  $\dot{EM}$  and  $\dot{UM}$ . The maximum number of lags for each variable was limited to four due to the small number of observations in the C-A sample. (The implausibly long lag lengths estimated by C-A—on the order of

<sup>5</sup>The estimated equation is

$$\begin{aligned} \dot{EM} = & 0.0935 + 0.202 \cdot \dot{M}_{-1} + 0.453 \cdot \dot{M}_{-2} \\ & + 0.0928 \cdot FEDV + 0.0291 \cdot UN_{-1}, \end{aligned}$$

where  $FEDV$  is normal federal expenditures as defined in Barro, and  $UN$  is  $\ln[U/(1-U)]$ ;  $R^2 = 0.838$ ,  $D-W = 2.196$ .

<sup>a</sup>Lag sum.

seven years or more for each industry—raise further questions about their findings.)<sup>6</sup>

The results shown in Table 3 provide some support for the alternative model of adminis-

<sup>6</sup>In personal correspondence, C-A responded to this charge by noting that others (for example, Michael Bordo, 1980) have found similarly long lags. In my view, this does not make their findings any more plausible. Theory can and should be used to rule out some results. For example, in many of the C-A regressions for the low- and medium-concentrated industries, some of the biggest positive coefficients are for money growth eight and nine years earlier, accounting for one-quarter to one-half the long-run effect, and larger than the impact after one or two years. I doubt any sensible model exists that would generate this pattern.

tered prices. Regardless of specification, the relative inflationary impact of  $\bar{U}M$  is always least in the most highly concentrated sector. While differences in sectoral responses to  $\bar{E}M$  are harder to detect, the impact of positive monetary shocks after one, two, or several years is always positive and always greater in the low- and medium-concentrated industries than their impact in those industries where  $CR4$  exceeds 70 percent. Indeed, for the latter group of firms, positive monetary shocks exert not only a smaller impact, but an often deflationary one. It is not clear why this should be the case, but a possible explanation may lie in the regression

results which generate the  $EM$  and  $UM$  series. While the Durbin-Watson statistic for that regression does not indicate a serious autocorrelation problem, the estimated correlation of the residuals is negative ( $\rho = -0.054$ ). Hence, positive monetary shocks in one period imply negative shocks in the next period. In turn, these later expected negative shocks will reduce the subsequent true anticipated money growth below the value implied by  $EM$ . In other words, money growth in excess of that anticipated could cause tacit colluders to revise downward both their estimate of future expected growth and their optimal price increases. As the bottom portion of Table 3 shows, the foregoing conclusions regarding the relative impact of  $EM$  and  $UM$  are not substantially altered by constraining the sum of the lagged coefficients on  $EM$  to be unity.

#### IV. Summary and Conclusions

The Chappell-Addison paper represents an important contribution to the administered-pricing debate. Nevertheless, their major conclusion that the theory of concentration-based administered prices is refuted by the evidence is overly strong. It is based on a comparison of mean lag statistics which, at best, only partially captures interindustry differences in price responsiveness and, at worst, is highly misleading. Reexamination of the C-A coefficient estimates does in fact show a substantially slower response of inflation to monetary growth in those industries where  $CR4$  exceeds 70 percent relative to the response in more competitive sectors.

A further reservation regarding the C-A findings stems from their failure to distinguish between expected and unexpected money growth. In a world in which inflation is primarily generated by money growth and in which expectations of that growth are at least somewhat rational, the administered-price thesis suggests that the real differences in industries' pricing behavior will lie in their separate responses to that part of money growth that is predictable and that part that is not, especially the latter. Using the data and the approach described by Barro, this

modification provides additional support for the administered-price thesis in that inflation in the highly concentrated sectors appears relatively more responsive to expected money growth than to unforeseen monetary shocks.

Both the results presented here and those of Chappell and Addison are somewhat tentative due to the small number of observations and other data limitations. Further research on administered pricing is clearly needed. Chappell and Addison are to be congratulated for providing a new and useful framework to guide that research. It is hoped that the modifications to that framework suggested here will also be helpful.

## Relative Prices, Concentration, and Money Growth: Reply

By HENRY W. CHAPPELL, JR. AND JOHN T. ADDISON\*

In his comment on our paper, Daniel Richards raises some interesting issues, but ones that are somewhat peripheral to the nature and scope of our original study. Richards makes two specific points of criticism. First, he notes that the mean lag is but one summary measure of the lag pattern, and that other such measures may indeed lead to alternative inferences being drawn from our data. Secondly, he conjectures that appropriate specification of the model should distinguish the effects of expected and unexpected money growth on sectoral inflation rates. In the light of these criticisms, he then reevaluates our empirical work, and concludes that there is rather more evidence in favor of the administered-pricing hypothesis than we reported.

Consider each point in turn. Richards states that "the fact that the mean lag comparisons contrast the time distribution of given total effects, without comparing the size of those total effects, is a crucial failure" (p. 274). By alternatively focusing on the coefficients for the first two lags of money growth and the sum of the coefficients on all lags, Richards finds that the prices of the high-concentration sector are the least responsive to money growth. But what is most clearly revealed by the results supplied by Richards in Table 1 is that most of our regressions do not preserve the long-run neutrality of money. This is the real lacuna of our own study. By the same token, the inferences drawn by Richards about "total effects" directly depend on this rather peculiar result. Rather than quickly conclude that the low-concentration sector is more responsive to money growth, we would instead argue that it would have been more appropriate at the outset to constrain the

lagged money coefficients to sum to unity. At our suggestion, Richards has estimated *OLS* equations in which this constraint is imposed. He does not replicate this procedure for the numerous Almon lag distributions employed in our original paper. We have. These regressions are consistent with Richards' findings as to the magnitudes of the first two coefficients. Also, the mean lags do appear to be shorter for the low concentration groups vis-à-vis the high-concentration group. Thus, while some revision of our conclusions may perhaps be in order, this is primarily due not to the deficiencies of the mean lag per se, but rather to the sensitivity of our results to the imposition of a long-run money neutrality constraint.

Even so, it should be emphasized that the evidence in favor of administered pricing remains very weak. As Richards notes, the coefficients on the  $M_{t-i}$  are never significantly different from zero, and the interequation differences also fail to achieve significance. That said, it is peculiar that, in Richards' results, as well as our own (from specifications imposing money neutrality), prices appear to be most responsive in the *medium*-concentration sector. Since most of the theoretical arguments relating market power to price adjustment would imply greater rigidity in markets where oligopolistic interdependence is most important (as opposed to either competitive or nearly monopolistic markets), this result is rather surprising. Perhaps future research (see below) will be able to explain this anomaly.

Richards also notes that the  $R^2$ s are consistently lower for the high-concentration group, from which he infers that prices in that sector are more independent of money growth. This is one possible interpretation, but there is an alternative that we find more compelling. The sectoral price indices are themselves averages of individual industry indices. In our sample, there were more industries in the low-concentration groups,

\*Department of Economics, University of South Carolina, Columbia, SC 29208. We acknowledge helpful comments from Geoffrey Wood and Michael Bordo, and the research assistance of Jane Pietrowski.

hence one would expect the averages for those groups to be less "noisy." This alone could explain the differences in  $R^2$  values.

We now turn to Richards' second point, namely that we should have distinguished between the anticipated and unanticipated components of money growth. We find this extension of our analysis novel in that it hints at the special problem of information confronting oligopolists seeking to maintain cartels in the face of changing economic conditions. It is this extension that differentiates his approach to administered pricing from ours. However, we have reservations about the empirical findings: our previous comments about money neutrality again apply—we have not reestimated these equations—while acute problems attach to the measurement of expected and unexpected money growth.<sup>1</sup> Empirically distinguishing between Richards' model of administered pricing and our own without far better data than currently exists would seem to be a nearly hopeless task.<sup>2</sup>

For the future, progress can possibly be made in recasting the administered-pricing debate, as suggested in our earlier paper. In particular, a fruitful line of inquiry would be to exploit the distinction between flexiprice and fixed price goods, first referred to by John Hicks. Such differences may or may not

be related to stylized market forms in any consistent fashion. We note that this distinction has proved fruitful in tackling a number of issues in the area of international finance.<sup>3</sup> A second issue, exploiting the anticipated/unanticipated money distinction, is whether oligopolists—who presumably wish to maintain the cartel—have stronger incentive to gather information to forecast events producing price changes than have firms in competitive industries.

<sup>3</sup>For example with respect to currency invoicing, the use of forward markets, and contract length. See Ronald McKinnon (1979) and Stephen Carse, John Williamson, and Geoffrey Wood (1980).

<sup>1</sup>The Barro method used by Richards to isolate the two components of money growth is fundamentally flawed (see, for example, Martin N. Baily, 1978). One obvious difficulty is of course that the model assumes that individuals form expectations on the basis of future information!

<sup>2</sup>Indeed, if anticipated money growth were only a function of lagged money growth rates, the models would be conceptually as well as empirically indistinguishable.

# Relative Risk Aversion in Comparative Statics: Comment

By ERIC BRIYS AND LOUIS EECKHOUDT\*

In a recent paper in this *Review*, Eliakim Katz (1983a) has convincingly argued that absolute and relative risk aversion should be measured in terms of terminal wealth and not as a function of changes in wealth (for example, profits).<sup>1</sup> By considering how a risk-averse competitive firm under price uncertainty reacts to an increase in the profits tax rate (with full loss offset), he has shown that its response depends upon the shape of both the absolute and relative risk aversion functions.

In this comment we indicate that Katz's suggestion to define utility in terms of final wealth should induce economists to pay attention to the very interesting, but so far little used, concept of partial relative risk aversion.<sup>2</sup> Indeed, as shown below, this concept is directly pertinent for the comparative statics analysis of a change in the profits tax rate. Besides, it gives some economic insight for a result that might otherwise look counterintuitive to many of us.

To the best of our knowledge, the notion of partial relative risk aversion was introduced by Carmen Menezes and David Hanson (1970),<sup>3</sup> who established the relationship between three measures of risk aversion (absolute; relative; partial relative) and the behavior of the risk premium under exogenous changes either in initial wealth or in the amount of risk (or both). More specifi-

cally, they proved that the properties of the partial relative risk-aversion function enable one to predict how the risk premium adjusts to a multiplicative transformation of the risk while initial wealth remains constant. It is immediately obvious that this notion is pertinent in Katz's problem, since for any output level, an increase in the tax rate on profits implies a multiplicative decrease in the risk faced by the firm without affecting its initial wealth. More precisely, by using a standard notation, final wealth ( $\bar{W}$ ) is equal to initial wealth ( $W_0$ ) plus after tax profits ( $\pi_t$ ), that is,

$$(1) \quad \bar{W} = W_0 + \pi_t \\ = W_0 + (1-t)(\bar{p}x - c(x) - B).$$

and, as shown by Katz,  $\text{sign}(dx^*/dt) = \text{sign}(\phi(W))$  where  $x^*$  stands for the optimal output level, and where

$$(2) \quad \phi(W) = -E[u''(W) \cdot (p - c'(x^*)) \\ \cdot (W - W_0)/(1-t)].$$

Now, using the partial relative risk-aversion function  $P(W_0, \pi_t)$ , defined by

$$(3) \quad P(W_0, \pi_t) = -\pi_t \\ \cdot u''(W_0 + \pi_t)/u'(W_0 + \pi_t),$$

it can be shown that an increasing  $P$  in terms of  $\pi_t$ , is sufficient to yield  $\phi(W)$  positive.<sup>4</sup> The technique of proof exactly parallels that used by Agnar Sandmo (1971) in a similar context, by considering first values of

\*Assistant Professor of Finance, CERAM, Sophia Antipolis/Valbonne, France, and Professor of Economics at Catholic Faculties of Mons, Belgium and Lille, France, respectively. We thank Pierre Hansen and Henri Loubergé for their help.

<sup>1</sup>As mentioned by Katz himself, this idea goes back to Kenneth Arrow (1965) and John Pratt (1964).

<sup>2</sup>As far as we know, this concept was used in comparative statics analysis by Peter Diamond and Joseph Stiglitz (1974), and by Joseph Hadar and William Russell (1978).

<sup>3</sup>In the same year, Richard Zeckhauser and Emmett Keeler defined the notion of "size-of-risk aversion" which is very close to the concept of partial relative risk aversion.

<sup>4</sup>As pointed out by Katz (1983b), one must be at least as careful in the use of  $P$  as in that of the relative risk aversion when it is defined as a function of  $\pi_t$  (instead of wealth). Indeed, when  $\pi_t$  can take negative values,  $P$  cannot be everywhere decreasing or constant in  $\pi_t$  under risk aversion.

$p$  inferior to the marginal cost evaluated at  $x^*$  (i.e.,  $c'(x^*)$ ) and then those superior to  $c'(x^*)$ . Thus under increasing partial relative risk aversion, a stronger fiscal pressure on profits induces risk-averse managers to increase output. This possibly counterintuitive result is very easily understood through the relationship between the partial relative risk aversion and the risk premium. When  $t$  increases, the amount of risk faced by the firm decreases,<sup>5</sup> so that under increasing partial relative risk aversion, the risk premium for the firm falls more than proportionately (see the main theorem in Menezes and Hanson). Consequently the firm is ready to assume more risk through a higher output level.

We should stress that the use of the concept of partial relative risk aversion does not contradict Katz's development but in fact puts it in another perspective. Indeed, defining the absolute ( $A$ ) and relative ( $R$ ) risk-aversion functions in terms of final wealth, one can show that<sup>6</sup>

$$(4) \quad \frac{dP}{d\pi_t} = \frac{dR}{d\pi_t} - W_0 \cdot \frac{dA}{d\pi_t}.$$

When  $R$  is nondecreasing and  $A$  nonincreasing (with at least one of them nonconstant),  $dP/d\pi_t$  is positive which, as shown above, is a sufficient condition to obtain a positive  $\phi$ . When both  $A$  and  $R$  are increasing (or decreasing),  $dP/d\pi_t$  is sign ambiguous and so is  $\phi$ .

Hence the conditions proposed by Katz in terms of  $A$  and  $R$  can be summarized in terms of  $P$ . Besides its convenience, the use of  $P$  has the advantage of giving a better economic insight about the behavior of the firm.

#### APPENDIX

A sufficient condition for  $\phi$  to be positive is that the partial risk-aversion function  $P$  is increasing in  $\pi_t$ .

#### PROOF:

For  $p \leq c'(x^*)$ , an increasing  $P$  implies

$$\begin{aligned} (A1) \quad & -(px^* - c(x^*) - B) \\ & \cdot (u''/u')(W_0 + px^* - c(x^*) - B) \\ & \leq -(c'(x^*) \cdot x^* - c(x^*) - B) \\ & \cdot (u''/u')(W_0 + c'(x^*)x^* - c(x^*) - B), \end{aligned}$$

and multiplying both sides by  $p - c'(x^*)$  reverses the inequality sign so that

$$\begin{aligned} (A1') \quad & -(p - c'(x^*))(px^* - c(x^*) - B) \\ & \cdot (u''/u')(W_0 + px^* - c(x^*) - B) \\ & \geq -(p - c'(x^*)) \cdot (c'(x^*) \cdot x^* - c(x^*) - B) \\ & \cdot (u''/u')(W_0 + c'(x^*)x^* - c(x^*) - B). \end{aligned}$$

For  $p \geq c'(x^*)$ , a relationship similar to (1') holds.

If we then multiply both sides by  $u'$  evaluated at  $(W_0 + px^* - c(x^*) - B)$  and if we take expectations, we get

$$\begin{aligned} (A2) \quad & E[-(p - c'(x^*))(px^* - c(x^*) - B) \\ & \cdot u''(W_0 + px^* - c(x^*) - B)] \\ & \geq -(c'(x^*)x^* - c(x^*) - B) \\ & \cdot (u''/u')(W_0 + c'(x^*)x^* - c(x^*) - B) \\ & \cdot E[u' \cdot (p - c'(x^*))]. \end{aligned}$$

As  $E[u' \cdot (p - c'(x^*))]$  is equal to zero by the first-order condition, we obtain the result that the left-hand side of (2) is nonnegative. But this expression is nothing but  $\phi(W)$  multiplied by  $(1 - t)$ .

# Relative Risk Aversion in Comparative Statics: Comment

By JOHN D. HEY\*

In his paper in this *Review*, Eliakim Katz (1983) confuses an error of logic with a possible error of empirical description: the "error," which he blames Agnar Sandmo (1971) of initiating, and myself (1981) among others of perpetrating, is clearly a case of the latter rather than an instance of the former. Nevertheless, his note, properly interpreted, does serve the important purpose of drawing attention to a hitherto neglected feature of the relative risk-aversion index. As a consequence, the significance of Sandmo's result (which remains logically correct) might now be viewed in a slightly different light.

Katz makes two substantive points concerning the relative risk-aversion index  $R$ ; the first relating to its definition; the second to its argument. Katz notes that Sandmo takes profit to be the relevant argument, which implies the following definition (compare Katz's equation (1)):

$$(1) \quad R = -\pi u''(\pi) / u'(\pi).$$

Katz then goes on to argue that "...the very definition of  $R$  as given in (1) is incompatible with decreasing or constant relative risk aversion," the reason being, according to Katz, that the "... $R$  associated with... negative profits will be negative and hence smaller than the positive  $R$  associated with positive profits" (p. 452).

Unfortunately, this argument fails to note that  $u''$  may change sign as  $\pi$  changes sign. For example, consider the case of *constant relative risk aversion*. If (1) is integrated twice, then we get

$$(2) \quad u(\pi) \propto \begin{cases} \pi^{1-R} & \pi \geq 0 \\ -(-\pi)^{1-R} & \pi \leq 0 \end{cases}$$

if  $0 < R < 1$ . (There are corresponding forms for  $R$  equal to or greater than 1.)

Clearly the utility function as given in (2) displays constant relative risk aversion as defined by (1). But, equally clearly, the utility function displays risk aversion for  $\pi > 0$ , risk neutrality for  $\pi = 0$  and risk loving for  $\pi < 0$ . Thus,  $u''$  changes sign at  $\pi = 0$ , as suggested by my discussion above. Katz's argument is clearly wrong.

The questions remain whether (2) is an (empirically) sensible utility function and whether it correctly encapsulates the intuitive notion of constant relative risk aversion. On the first question, a glance at Daniel Kahneman and Amos Tversky (1979, especially p. 279) suggests that it is by no means implausible; as to the second, the intuitive notion that needs to be captured is the idea that the proportional risk premium is independent of the scale of the gamble (see John Pratt, 1964, Sections 11 and 12). Thus, for example, if the individual is indifferent between a gamble involving a 50-50 chance of  $kx_1$  or  $kx_3$  and a certainty of  $kx_2$  ( $x_1 < x_2 < x_3$ ) for  $k=1$ , then he should also be indifferent for  $k=2$  or  $k=3$ , or, indeed, for any value of  $k$ —whether positive or negative. But this requirement leads precisely to the utility function (2). For instance, if  $R = \frac{1}{2}$ , then the individual is indifferent between a 50-50 chance of  $\pi = 9$  or  $\pi = 16$  and a certainty of  $\pi = 12\frac{1}{4}$ ; similarly, the individual is indifferent between a 50-50 chance of  $\pi = 18$  or  $\pi = 32$  and a certainty of  $\pi = 24\frac{1}{2}$ ; but equally, the individual is indifferent between a 50-50 chance of  $\pi = -9$  or  $\pi = -16$  and a certainty of  $\pi = -12\frac{1}{4}$ . Thus, as I have already noted, the individual is risk loving for  $\pi$  negative—as Kahneman and Tversky have noted, a not uncommon phenomenon.

The result of Sandmo which Katz asserts is based on an error states that "an increase in a proportional profits tax (with full loss offset) will reduce, leave unchanged or increase the firm's output according as relative

\*Department of Economics and Related Studies, University of York, York YO1 5DD England.

risk aversion  $R$  is increasing, constant or decreasing" (p. 452). Consider the case when  $R$  is constant, and thus the relevant utility function that given in (2). The objective function,  $Eu(\pi)$ , in this case is given by

$$\begin{aligned} & \int_{p=-\infty}^{c(x)/x} \{-[px - c(x)](1-t)\}^{1-R} \\ & \quad \times f(p) dp + \int_{p=c(x)/x}^{\infty} \{[px - c(x)] \\ & \quad \times (1-t)\}^{1-R} f(p) dp \\ & = (1-t)^{1-R} \left\{ \int_{p=-\infty}^{c(x)/x} \{-[px - c(x)]\}^{1-R} f(p) dp \right. \\ & \quad \left. + \int_{p=c(x)/x}^{\infty} [px - c(x)]^{1-R} f(p) dp \right\}, \end{aligned}$$

from which it is clear that the value of  $t$  does not affect the optimal choice of  $x$ . Thus Sandmo is right. Similarly, the rest of Sandmo's result is correct.

Katz is clearly at liberty to generalize Sandmo's result, which he has done by postulating some initial wealth  $W_0$ . However, he should note that nowhere in his proofs has he imposed the condition that  $W$  ( $\equiv W_0 + \pi$ ) be positive. Thus, Katz's  $R$  could suffer from the same "problem" as Sandmo's  $R$ ; hence, it must come as something of a relief to Katz to learn that there was no problem in the first place!

However, Katz is not at liberty to suggest that certain combinations of signs on  $dA/dW$  and  $dR/dW$  are "nonfeasible" (see his ta-

ble, p. 453). Since  $R$  and  $A$  are related by  $R(W) = WA(W)$ , it follows that

$$(3) \quad dR/dW = A + WdA/dW.$$

If  $A$  and  $W$  are allowed to take positive or negative values, it is clear that any combinations of signs on  $dR/dW$  and  $dA/dW$  are possible. Even with  $W$  restricted to be positive,  $dA/dW$  can be positive while  $dR/dW$  is negative—as long as  $A$  is negative. Surely Katz does not consider that risk lovers are "nonfeasible"?

Thus, this comment shows that Katz is in error in attributing an error to Sandmo and others. But Katz does indirectly draw attention to a feature of the relative risk-aversion index, for negative values of its argument, which was not hitherto realized or appreciated.

# Relative Risk Aversion in Comparative Statics: Reply

By ELIAKIM KATZ\*

The comment by Eric Briys and Louis Eeckhoudt represents an elegant reformulation of my earlier results and makes, in my view, a useful point. In contrast, the comment by John Hey is misleading. My 1983 paper is perfectly correct for risk-averse firms. The results by Agnar Sandmo (1971) and by Hey (1981) *explicitly* pertain to risk-averse firms. Hence the claim I make in my paper is fully valid.

In my earlier paper I showed that there has been a recurrent error in the literature dealing with risk-averse firms under uncertainty. For example, I show that Hey is wrong in making the statement that "*If the firm is risk averse, then the imposition of an ad-valorem tax on the objective function  $Y$  (or an increase in the rate of such a tax) will cause the firm to increase, keep unchanged or to decrease its value of  $X$  according as its index of relative risk aversion is increasing, constant or decreasing*" 1981, p. 370, emphasis added). Similarly Sandmo is wrong in combining the assumption that " $U''(\pi) < 0$ " (p. 66), with the statement that "increasing the tax rate will increase, leave constant or reduce output according as relative risk aversion is increasing, constant or decreasing" (p. 70).

Despite his obvious eagerness to absolve himself of having made an error, Hey (his comment resting on a utility function which requires *both* risk-loving and risk-averse behavior), does not (indeed cannot) make the above irrefutably wrong statements correct. Hence, it takes considerable chutzpah for Hey to claim that I am in error in attributing an error to Sandmo and others.<sup>1</sup>

Indeed, given the universally accepted assumption of risk aversion (which assumption was adopted by both Sandmo and Hey in the above quoted statements) both the point I make and the table I supply in my earlier paper are perfectly correct.

Other than repeating the claim that I am wrong, in error or confused, Hey attempts in his comment to find a utility function for which his results hold, to replace the concave utility function he now finds troublesome. It seems, however, that pickings in this area are rather slim. I leave it to the reader to judge the plausibility of a utility function wherein firms are *always* risk averse in the region of profits and *always* risk loving in the region of losses.

Finally, I should like to make one qualification to the solution offered in my paper to the problem of using a profits-based definition of risk aversion. It is not, as Hey suggests, that the solution fails when wealth is negative, since, in general, wealth is bounded below by zero. Rather, it transpires that for positive absolute risk aversion, it is always possible to find a *positive* wealth for which relative risk aversion *must* be increasing. To see this, note that relative risk aversion is equal to  $WA(W)$  where  $A(W)$  is absolute risk aversion. Hence, differentiating relative risk aversion with respect to  $W$  yields  $WA'(W) + A(W)$ , so that if  $W$  is sufficiently near zero, relative risk aversion must be increasing.

## NOTES

The twelfth annual AEA Summer Program for Minority Students will be held June 17–August 9, 1985, at the University of Wisconsin-Madison. The program is open to black, Hispanic, and native American graduate students in economics, and offers intensive instruction in the core areas essential for graduate study. Students need not be economics majors, but must have completed one year of economic principles. Preference will be given to those who have also completed one year of calculus. Although the program is designed primarily for students completing the junior year, sophomores and seniors are also encouraged to apply. Participants will receive tuition, room and board, transportation, and a cash stipend. For further information and application materials, write to AEA Summer Program, Department of Economics, University of Wisconsin, 1180 Observatory Drive, Madison, WI 53706 (telephone 608+263-2441).

Commencing July 1, 1986, *SOCIETY*, the periodical of record in the social sciences, will shift to a rotating editorship. Applications for the stewardship of this publication are encouraged from qualified professionals from any of the major disciplines in social science. Since production, marketing, and fulfillment will continue to be performed at Transaction, geographic locale need not be a central consideration for candidates. Any individual interested in this position should file the following information by July 1, 1985: a brief narrative of accomplishments, including a statement of personal goals; professional resume of past appointments and writings; and a statement of resources that would be provided by your home university or institution in support of your performance of *SOCIETY*'s editorial functions. The new editor will have complete editorial autonomy in determining the contents of the periodical, and the opportunity to select a new editorial board. A modest honorarium in recognition of his or her activities will be available. Send your response directly to Irving Louis Horowitz, President, Transaction/*SOCIETY*, Rutgers University, New Brunswick, NJ 08903. Please, no telephone inquiries. All materials received will be kept confidential.

The Bureau of the Census in conjunction with the National Science Foundation and Yale University has developed a longitudinal database file of annual survey response data for individual manufacturing establishments. Initially, the Longitudinal Establishment Data (LED) File will contain annual data for the period 1972 through 1981. The source of the data for 1972 and 1977 is the Census of Manufacturers. The LED File will be updated regularly to contain data from those sources. The LED File makes available to the economic research community economic time-series of annual data for

manufacturing establishments in a form conducive to research and development. Considerable effort is being made to minimize the time and cost of maintaining the confidentiality of individual establishments requiring that estimation and computation using individual micro-data be conducted at the Census Bureau and the results screened to prevent disclosure. For additional information, contact James L. Monahan or J. R. Norsworthy, Center for Economic Studies, Bureau of the Census, Washington, D.C. 20233 (telephone 301 + 763-5684).

The Rockefeller Foundation offers grants of \$15,000 to \$30,000 to support their Program to Explore Long-Term Implications of Changing Gender Roles. Projects may examine factors that address the social, psychological, political, and/or economic phenomena associated with the rapidly changing status of women, or analyze ways in which policy may respond to these changes. Scholars and practitioners who have completed their training may apply. Awards cannot be given for completion of degree training. Proposals involving more than one investigator or more than one institution are welcome. Deadlines are March 15 and September 15, 1985. Address inquiries to Gender Roles Program, The Rockefeller Foundation, 1133 Avenue of the Americas, New York, NY 10036.

The third Biennial Conference on East Central Europe, Russia, and the Soviet Union will be held March 28–30, 1985, in Sarasota. It is sponsored by New College of the University of South Florida in Sarasota, Florida.

*Call for Papers:* The European Finance Association will hold its twelfth annual meeting, August 29–31, 1985, at the University of Bern. To serve as a chairperson, discussant, or to present a paper (copies of detailed abstracts must be sent by April 1), contact Professor Walter Wasserfallen, University of Bern, Volkswirtschaftliches Institut, Länggass-Strasse 8, 3012 Bern, Switzerland.

*Call for Papers:* The third annual meeting of the Association of Managerial Economists (AME) will be held in New York, December 29–30, 1985. Three sessions of competitively selected papers will be featured in conjunction with the ASSA meetings. Especially encouraged are papers integrating the theory of accounting, finance and industrial organizations. Submission deadline is June 15, 1985. Members and nonmembers are invited to submit papers and/or make program sugges-

tions to Professor Mark Hirschey, AME Program Chair, Graduate School of Business Administration, 1100 14th Street, University of Colorado, Denver, CO 80204 (telephone 303 + 623-4436).

---

*Call for Papers:* The twelfth annual conference of the European Association for Research in Industrial Economics will be held September 11-13, 1985, at the Department of Applied Economics, University of Cambridge. Sessions will include economics of industry and firm organization, industrial and competition policy, industrial and international trade, industry studies, regulation of industries and firms, as well as other areas of current interest in industrial economics. To present a paper, send three copies by April 1, 1985, to the Chairman of the Programme Committee, Dr. A. Singh, University of Cambridge, Department of Applied Economics, Sidgwick Avenue, Cambridge CB3 9DE, England.

---

*Call for Papers:* *Studies in Economic Analysis* is a biannual, student-edited journal soliciting research articles from both established economists and students. Submission fee is \$3.00 for nonsubscribers. Submit manuscripts to, or request format and style instructions from, The Editors *SEA*, Department of Economics, College of Business Administration, University of South Carolina, Columbia, SC 29208.

---

*Call for Papers:* The IREDU (Centre National de la Recherche Scientifique) is sponsoring an international conference, "Economics of Education: Tackling the New Policy Issues," to be held June 1986 in Dijon, France. The cosponsor is *The Economics of Education Review*. Send 1-2 page abstracts with a brief resume. Although papers dealing with developed countries will be considered, those on less developed countries will receive higher priority. Send abstracts no later than May 15, 1985, to Benoit Millot, IREDU, Faculte des Sciences-Mirande, 21004 Dijon, Cedex France.

---

World Congress of Public Finance of IIPF (International Institute of Public Finance) will be held in Madrid, August 26-30, 1985. The topic is "Public Finance: Issues and Prospects." The IIPF invites nonmembers to contribute. Contact Professor Horst Claus Recktenwald, Friedrich-Alexander-Universität Erlangen-Nürnberg, Lange Gasse 20, 8500 Nürnberg, Germany (telephone 0911 + 5302-200), or Professor H. M. van de Kar, Erasmus University, Rotterdam, Postbus 1738, 3000 DR Rotterdam, Netherlands.

---

A session on property rights analysis will be held at the 1985 meetings of the Law and Society Association,

June 6-9, San Diego, California. Any paper developing or applying property rights theory is suitable, but selection will favor those that link traditionally separate areas of the social sciences. Contact Professor David Schap, Department of Economics, College of the Holy Cross, Worcester, MA 01610.

---

The Association for Canadian Studies in the United States (ACSUS) will hold its eighth biennial conference on September 19-21, 1985, at the Franklin Plaza Hotel, Philadelphia, Pennsylvania. All areas of Canadian studies will be represented. For further details, contact the national office: ACSUS, One Dupont Circle, Suite 620, Washington, D.C. 20036 (telephone 202 + 887-6375).

---

To inaugurate its economics research program, GTE Laboratories will hold a symposium on industrial organization in Waltham, Massachusetts, August 15-16, 1985. (It immediately precedes the World Congress of the Econometric Society to be held in Cambridge.) Those interested in attending should contact Dr. Joseph Farrell, GTE Laboratories Inc., 40 Sylvan Road, Waltham, MA 02254.

---

Economists who are strongly oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings held outside the United States, Mexico, and Canada that are concerned with the humanistic aspects of their discipline are eligible to apply for small travel grants of the American Council of Learned Societies. Financial assistance is limited to air fare between major commercial airports and will not exceed one-half of projected economy-class fare. Social scientists and legal scholars who specialize in the history or philosophy of their disciplines are eligible if the meeting they wish to attend is so oriented. Applicants must hold a Ph.D. degree or its equivalent, and must be citizens or permanent residents of the United States. To be eligible, proposed meetings must be broadly international in sponsorship or participation, or both. The deadlines for application to be received in the ACLS office are: meetings scheduled between July and October, March 1; for meetings scheduled between November and February, July 1; for meetings scheduled between March and June, November 1. Please request application forms by writing directly to the ACLS (Attention: Travel Grant Program), 800 Third Avenue, New York, NY 10022, setting forth the name, dates, place, and sponsorship of the meeting, as well as a brief statement describing the nature of your proposed role in the meeting.

Wayne Carroll: assistant professor, Ohio State University, January 1, 1984.

Garey Durden: professor of economics, Appalachian State University, July 1, 1984.

Yiu-Kwan Fan: professor of economics, University of Wisconsin-Stevens Point, August 1984.

William Guthrie: associate professor of economics, Appalachian State University, July 1, 1984.

Bruce Hamilton: professor of economics, Johns Hopkins University, July 1, 1983.

James F. Haynes: associate professor of economics, Athens State College, September 1, 1984.

R. Bryce Hool: professor of economics, State University of New York-Stony Brook, September 1, 1984.

Shafiqul Islam: chief, Industrial Economics Division, International Research Department, Federal Reserve Bank of New York, July 26, 1984.

Arnold Katz: professor of economics, University of Pittsburgh, September 1984.

Masahiro Kawai: associate professor of economics, Johns Hopkins University, July 1, 1984.

Robert T. McGee: associate professor of economics, Florida State University, August 3, 1984.

Yoshimasa Nomura: assistant professor, Ohio State University, April 1, 1984.

Jack Ochs: professor of economics, University of Pittsburgh, September 1984.

Timothy Perri: associate professor of economics, Appalachian State University, July 1, 1984.

Frank J. P. Pinto: Interregional Energy Adviser, Natural Resources and Energy Division, Department of Technical Co-operation for Development, United Nations, July 1, 1984.

Peter Skaperdas: senior economist, fiscal analysis staff, Domestic Research Department, Federal Reserve Bank of New York, May 3, 1984.

Mark Walker: professor of economics, State University of New York-Stony Brook, September 1, 1984.

#### Administrative Appointments

Edward L. Claiborn: head of economics, Virginia Military Institute, August 1984.

Thomas S. McCaleb: assistant vice president of academic affairs, Florida State University, August 3, 1984.

#### New Appointments

David M. Anderson: instructor of economics, Iowa State University, August 21, 1984.

Michael J. Applegate: visiting associate professor of economics, Iowa State University, August 1, 1984.

Charles Bates: assistant professor of economics, Johns Hopkins University, July 1, 1984.

Elaine Bennett: visiting assistant professor, University of Pittsburgh, September 1984.

Erik C. Benrud: instructor of economics, Virginia Military Institute, August 1984.

Aninda Bose, State University of New York-Stony Brook: instructor, Ohio State University, October 1, 1984.

Raymond T. Brastow, University of Washington: visiting assistant professor of economics, University of Puget Sound, September 1984.

T. J. Chen, Pennsylvania State University: assistant professor of economics, University of Mississippi, fall 1983.

Soo Hong Chew: assistant professor of economics, Johns Hopkins University, July 1, 1984.

Patricia Karr Cohen, University of North Carolina-Chapel Hill: assistant professor of economics, University of Mississippi, fall 1983.

Roger Cohen, University of North Carolina-Chapel Hill: assistant professor of economics, University of Mississippi, fall 1983.

Thomas Coleman: assistant professor of economics, State University of New York-Stony Brook, September 1, 1984.

Robert Curran: economist, Developing Economics Division, External Financing Department, Federal Reserve Bank of New York, August 15, 1984.

Larry R. Dale: associate professor of economics, West Texas State University, August 1984.

Joseph S. DeSalvo: director, Center for Economic and Management Research, University of South Florida, September 1, 1984.

Nestor Dominquez: economist, fiscal analysis staff, Domestic Research Department, Federal Reserve Bank of New York, August 20, 1984.

Ellen Evans: economist, International Financial Markets Division, Financial Markets Department, Federal Reserve Bank of New York, September 10, 1984.

James R. Follain: professor of finance, University of Illinois-Urbana, August 20, 1984.

Paul B. Ginsburg, Congressional Budget Office: senior economist, Rand Corporation, August 1984.

Jeremy Gluck: economist, International Financial Markets Division, Financial Markets Department, Federal Reserve Bank of New York, July 9, 1984.

John K. Green, East Carolina University: associate professor of accounting, Washington and Lee University, July 1, 1984.

Joseph Harrington: assistant professor of economics, Johns Hopkins University, July 1, 1984.

Leonard F. Herk: assistant professor of economics, Florida State University, August 3, 1984.

Harold Hotelling, University of Kentucky: assistant professor of economics, Oakland University, August 15, 1984.

Jerry W. Johnson: visiting professor of economics, Iowa State University, August 21, 1984.

Andrew S. Joskow, Yale University: economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice, September 1984.

Nancy Kane: economist, Developing Economies Division, External Planning Department, Federal Reserve Bank of New York, September 5, 1984.

Barbara H. Kehrer, The Robert Wood Johnson Foundation: vice president, The Henry J. Kaiser Family Foundation, October 1, 1984.

Michael Kennedy, University of Texas-Austin: senior economist, Rand Corporation, January 1984.

Henry B. McFarland, U.S. International Trade Commission: economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice, April 1984.

Brian H. McGavin: assistant professor of economics, Florida State University, August 3, 1984.

R. Timothy McGee: economist, Business Conditions Division, Domestic Research Department, Federal Reserve Bank of New York, May 9, 1984.

Therese McGuire: assistant professor of economics, W. Averell Harriman College for Policy Analysis and Public Management, State University of New York-Stony Brook, January 1, 1985.

John Mangel, University of Georgia: visiting assistant professor of economics, University of Mississippi, 1984-85.

Roy E. Marden: corporate economist, Philip Morris, Inc., June 1983.

Kent W. Mikkelsen, University of Michigan: economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice, May 1984.

Hajime Miyazaki, Stanford University: associate professor, Ohio State University, October 1, 1984.

Peter Mueser: assistant professor of economics, Johns Hopkins University, July 1, 1983.

Carl R. Neu, First National Bank of Chicago: economist, Rand Corporation, September 1984.

Daniel Nolle: economist, Industrial Economies Division, International Research Department, Federal Reserve Bank of New York, September 10, 1984.

Esmail Noori, University of Colorado: visiting assistant professor of economics, University of Mississippi, 1984-85.

Robert Porter: associate professor of economics, State University of New York-Stony Brook, September 1, 1984.

David L. Redden: instructor of economics, Virginia Military Institute, August 1984.

Duane J. Rosa: instructor of economics, West Texas State University, August 1984.

Robert Rosenthal: professor of economics, State University of New York-Stony Brook, September 1, 1984.

Christopher Rude: economist, Industrial Economies Division, International Research Department, Federal Reserve Bank of New York, September 10, 1984.

Merrile Sing, University of Wisconsin: economist, Economic Policy Office, Antitrust Division, U.S. Department of Justice, October 1984.

Kathleen J. Stirling, University of Notre Dame: assistant professor of economics, University of Puget Sound, September 1984.

Daniel D. Tatar: instructor of economics, Virginia Military Institute, August 1984.

Kuo-Chiang John Wei, University of Illinois: assistant professor of economics and finance, University of Mississippi, fall 1983.

Edward Zakkak, Louisiana State University-Baton Rouge: visiting assistant professor of finance, University of Mississippi, 1984-85.

#### Leaves for Special Appointments

Walter Enders, Iowa State University: University of California-San Diego, August 21, 1984-May 20, 1985.

Edi Karni, Johns Hopkins University: department of economics, Tel-Aviv University, 1984-85.

James R. Prescott, Iowa State University: Federal Bank of Kansas City, August 21-December 31, 1984.

#### Resignations

Peter L. Kahn, Ohio State University, September 1984.

M. Ali Khan, Johns Hopkins University: University of Illinois-Urbana, July 1, 1984.

Frank Lysy, Johns Hopkins University: World Bank, July 1, 1984.

Charles Miller, Johns Hopkins University, July 1, 1983.

Frederick Miller, Johns Hopkins University: Braxton Associates, Boston, January 1, 1984.

Thomas A. Wolf, Ohio State University, June 1984.

## NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories (please—do not send public relation releases):

- |   |   |
|---|---|
| 1—Deaths  | 6—New Appointments                                  |
| 2—Retirements                                   | 7—Leaves for Special Appointments (NOT Sabbaticals) |
| 3—Foreign Scholars (visiting the USA or Canada) | 8—Resignations                                      |
| 4—Promotions                                    | 9—Miscellaneous                                     |
| 5—Administrative Appointments                   |   |

B. Please give the name of the individual (SMITH, Jane W.), her present place of employment or enrollment: her new title (if any), new institution and the date at which the change will occur.

C. Type each item on a separate 3×5 card.

D. The closing dates for each issue are as follows: *March*, October 15; *June*, January 15; *September*, April 15; *December*, July 15.

All items and information should be sent to the Assistant Production Editor, *American Economic Review*, Room 8279, Bunche Hall, University of California, Los Angeles, CA 90024.

# MACROECONOMIC CONFLICT AND SOCIAL INSTITUTIONS

**Shlomo Maital and Irwin Lipnowski, Editors**

The works included in MACROECONOMIC CONFLICT AND SOCIAL INSTITUTIONS speak with a common voice on how people, as individuals and in groups, affect the outcome of macroeconomic contests. Using game theory models the authors analyze macroeconomics through matrices relating government, business, and labor interests working toward a final goal of mutually beneficial results.

The distinguished contributors include David C. Colander, Kenneth J. Koford, Clive Bull, Andrew Schotter, Paul Davidson, Benjamin Bental, Steven Plaut, Noah M. Meltz, Jeffrey B. Miller, Jerrold E. Schneider, and the editors, Shlomo Maital and Irwin Lipnowski.

1984—248 pages—\$29.95—ISBN 0-88730-034-0

# NEOCLASSICAL POLITICAL ECONOMY

**An Analysis of Rent-Seeking  
and DUP Activities**

**David C. Colander, Editor**

*Contributors include:* Mancur Olson, Jagdish N. Bhagwati, Richard A. Brecher, T.N. Srinivasan, Douglas North, Stephen P. Magee, Warren J. Samuels, Nicholas Mercuro, Michael S. McPherson, Ronald Findlay, Stanislaw Wellisz, Harold Demsetz, Elias Dinopoulos, Frederic L. Pryor, William A. Brock, Gary M. Anderson, Robert Tollison, Kenneth Koford, James T. Bennett, Thomas J. DiLorenzo, Gordon Tullock, and David C. Colander

1984—288 pages—\$32.00—ISBN 0-88410-999-2

## Understanding Marx

*A Reconstruction and Critique of Capital*

Robert Paul Wolff

"This book is a *tour de force*. The author presents the Classical-Marxian theory of value and distribution in a manner completely accessible to those innocent of modern algebra, yet without any sacrifice of content. Moreover, he sets the argument in its philosophical context, thereby adding an important dimension usually missing in economic theorizing."

—Edward J. Nell, *New School for Social Research*

*Studies in Moral, Political, and Legal Philosophy*  
Marshall Cohen, Editor

246 pages. C: \$25.00. P: \$7.95

# UPDATE

## **Comparative Economic Systems Second Edition**

**Paul R. Gregory**

University of Houston, College Park

**Robert C. Stuart, Rutgers —**

The State University of New Jersey

About 450 pages • cloth • Instructor's Manual  
with Test Items • Just published

Gregory and Stuart's Second Edition offers full, balanced treatment of the theories of capitalism and socialism, illuminated with major case studies of systems in the United States, the Soviet Union, and Yugoslavia. Using a consistent framework for analysis, the authors present their material in a manner that allows students to make significant comparisons among systems.

A major revision, the Second Edition presents a thoroughly up-to-date treatment of capitalism, examines the energy crisis of the 1970s and its impact today, offers a new chapter on Yugoslavia's market socialism, and fully covers international trade. Diverse features of economic systems are clarified through studies of numerous countries, including both East and West Germany, Hungary, France, Great Britain, China, and Japan.

## **Domestic Transportation: Practice, Theory, and Policy Fifth Edition**

**Roy J. Sampson, University of Oregon**

**Martin T. Farris and David L. Shrock**

Both of Arizona State University

About 640 pages • cloth • Instructor's Manual  
Just published

A best seller in the field, *Domestic Transportation* integrates application with theory and policy, and is therefore suitable for both business administration and economics students. Updated throughout, the Fifth Edition includes new chapters on passenger transportation, international transportation, and carrier management, plus a detailed discussion of the effects of recent deregulation developments.

## **Macroeconomics**

**Norman C. Miller**

University of Pittsburgh

734 pages • Study Guide • Instructor's Manual  
1983

Miller presents all the theory, facts, empirical evidence, ideas, policy discussions, and applications necessary so students can understand economic issues and related government policy. Up-to-date, the text covers supply-side economics and international economics and is thoroughly objective in its discussions of current economic controversies.

Special pedagogical features for each chapter help students to learn and retain macroeconomic theory and apply this knowledge to current issues.

## **The Management of Financial Institutions**

**Benton E. Gup, University of Alabama**

530 pages • cloth • Instructor's Manual  
1984

Focusing upon management techniques common to the broad range of financial institutions of the 1980s, Gup's timely new text treats bank management as a useful model for other types of financial management. The practical application of theory is stressed throughout.

Chapter outlines and lists of important concepts help guide student learning.

## **Cases in Financial Management Second Edition**

**Jerry A. Viscione and George A. Aragon**

Both of Boston College

581 pages • cloth • Instructor's Manual  
1984

For adoption consideration, request examination copies from your regional Houghton Mifflin office.

## **Houghton Mifflin Company**

# DEFY THE LAWS OF ECONOMETRICS.

Somewhere it is written that large-scale econometric applications require large computers. That the necessary speed and accuracy are available only on a mainframe.

It is also accepted that econometric software must be difficult to learn and complex to use. And that sizeable monthly time-sharing fees are a simple fact of life.

With all due respect to these principles of the past, we proudly present what's new: ESP™ The Econometric Software Package™ from Alpha Software®. It's a full-scale, fast and highly accurate IBM® PC and XT version of the well-known ESP mainframe program.

And it's already been selected for use by Chase Econometrics, Prudential-Bache and New York Telephone, among others.

Why? Because nothing of the mainframe program is sacrificed. You get the analytical tools you need for sophisticated modeling and forecasting. Nearly all accepted statistical and regression techniques are at your command in one truly powerful program.

In fact, ESP from Alpha is actually enhanced with features like built-in graphics and advanced data management. Plus, ESP interacts like the best personal computer software—with a spontaneous, natural feel that's instinctive, and easy to grasp. It even has on-line help and tutorials.

ESP lets you download from any major data bank including Chase and DRI. Or move your own data from other PC software like 1-2-3® Multiplan® dBASE II® and our own Data Base Manager II™.

But what's best is ESP gives you nearly instant results. Any analysis is performed before your eyes. Models, forecasts, scenarios—as many as you'd like, as often as you'd like, any time you'd like. At no incremental cost.

And you pay just \$795 for ESP from Alpha.

For more information and a demonstration version of ESP, send \$5.00 to Alpha Software Corporation, 30 B Street, Burlington, MA 01803. Or call us at 1-800-451-1018 (in Massachusetts call 1-800-462-2016).

# ALLEN & UNWIN

## APPRAISAL AND CRITICISM IN ECONOMICS

A Book of Readings  
Bruce Caldwell, Editor

A major new collection of writings by economists and philosophers on the methodology of economics. The first part contains classic articles from the positivist era from Hutchinson, Machlup, Friedman and Samuelson. Part Two covers the wide range of post-positivist contributions, including Blaug, Boland, McCloskey and Caldwell. *Paper \$12.95 Cloth \$29.50 490pp. 1984*

## KEYNESIANISM VS. MONETARISM

And Other Essays in Financial History  
Charles P. Kindleberger

"Charles Kindleberger — one of those rare beings who can move with equal ease in high theory or low history." *Barry Supple, Times Literary Supplement*

This volume brings together Professor Kindleberger's characteristically readable and stimulating essays on a wide range of topics and ideas from the financial history of the last 200 years. *Cloth \$27.50 200pp. Summer 1985*

## METHODOLOGY FOR A NEW MICROECONOMICS:

The Critical Foundations  
Lawrence A. Boland

Boland critically examines existing neoclassical paradigms of equilibria and concludes that so far no one has provided a satisfactory methodological individualistic explanation of market stability. His important new work focuses on the inherent methodological issues which must be overcome in developing innovative approaches to neoclassical economics. *Cloth \$28.50 224pp. Summer 1985*

## THE ECONOMIC ANALYSIS OF TRADE UNIONS

New Approaches and Evidence  
Barry T. Hirsch and John T. Addison

This new text reviews the burgeoning literature on labor unions and examines the effect unions had on relative wages, earnings distribution, productivity, inflation and politics. Hirsch and Addison view unions as determined by past and present worker and industry characteristics, the legal environment and other factors. *Paper \$10.95 Cloth \$27.50 256pp. 1985*

## SILICON LANDSCAPES

Peter Hall and Ann Markusen, Editors

Experts from the U.S. and the U.K. focus on the new regional development success stories — Silicon Valley, Boston's Route 128, and Britain's M4 Corridor. Their studies examine the ingredients for their success, the nature and demands of "High-Tech" industries, and their effect on local economies. *Paper \$9.95 Cloth \$25.00 160pp. February 1985*

# AEA sponsored Group Life Insurance for you and your family— at attractive rates!

The AEA Group Life Insurance Plan can help provide valuable supplementary protection—at attractive rates—for eligible members and their dependents.

Because AEA participates in a large Insurance Trust which includes other scientific and technical organizations, the low cost may be even further reduced by premium credits. In the past eight years, insured members received credits on their April 1 semiannual payment notices averaging over 44% of their annual premium contributions. (These credits are based on the amount paid during the previous policy year ending September 30.) Of course future premium credits, and their amounts, cannot be promised or guaranteed.

Now may be a good time for you to re-evaluate your present coverage and look into AEA Life Insurance. Just fill out and return the coupon for more details at no obligation.

# JOURNAL OF MONEY, CREDIT, AND BANKING

## Data Storage and Evaluation Project

The *Journal of Money, Credit, and Banking* Data Storage and Evaluation Project, which is supported by National Science Foundation grant number SES-8112800, provides for the collection of data sets and programs used in selected empirical articles appearing in the journal. About two-thirds of *JMCB* articles are empirical. The aim of the project is to evaluate findings through replication of data from original sources and replication of empirical results. Data sets are available to researchers at marginal cost.

Data sets from empirical articles published in 1983 and subsequently are available as well as data from selected articles published in earlier years. A complete list of data sets now available can be obtained from the *JMCB* editorial office.

Send inquiries to: Editorial Office, *Journal of Money, Credit, and Banking*, Department of Economics, Ohio State University, 1775 College Road, Columbus, Ohio 43210-1309. Telephone: 614-422-7834.

*The real world  
comes to the classroom . . .*

# **Robert J. Barro**

*University of Rochester*

## **MACROECONOMICS**

Barro's *Macroeconomics* is the first modern presentation of the market clearing approach to macroeconomics. It provides an honest and realistic alternative to the cumbersome and unrewarding IS/LM approach of current intermediate texts.

"Robert Barro has been a leading contributor to recent developments in the analysis of the overall behavior of the economy. He has now written a lucid, comprehensive, and authoritative exposition of the current state of our understanding of these phenomena. His text covers both the latest theoretical developments and the latest empirical evidence. It can be highly recommended on both levels."

—Milton Friedman,  
Senior Research Fellow  
Hoover Institution on War, Revolution and Peace  
Stanford University

" . . . What Barro does is not only build a macroeconomic model from the ground up but also one that is meant to explain observed economic phenomena . . . if only other textbook authors would try harder to do this, students would learn more and teachers would find their job much easier."

—James Barth,  
The George Washington University

1984    580 pp.

You owe it to yourself and your students to examine this important new text. To request a complimentary copy, write to Lisa Berger, Dept. 5-1926. Please include course name, enrollment, and title of present text.

**R. Carter Hill**, *University of Georgia*

**Helmut Lütkepohl**, *Universität Osnabrück*

**Tsoungh-Chao Lee**, *University of Connecticut*

Now the most complete treatment of major econometric problems has been revised and updated. The authors present the most systematic and up-to-date view of econometric problems, their statistical consequences, remedies, alternatives, and future research. Includes new chapters on asymptotic distribution theory, Bayesian inference, time series, and simultaneous equation statistical models. The distribution lag chapters have been rewritten to tie-in with time-series chapters.

## **Books that matter are Basic.**

### **Thinking Economically**

**How Economic Principles Can Contribute to Clear Thinking**

**MAURICE LEVI**

In this witty and beautifully written book, Maurice Levi shows us with a wealth of interesting real-life examples exactly how economists approach problems and how "thinking economically" can help us make better decisions. Economic thinking, according to Levi, need not be—and indeed should not be—restricted to abstract problems or government level policy making. "A valuable and clearly written book that shows the great benefits of using economics in day-to-day thinking."—JACOB A. FRENKEL, University of Chicago.

\$16.95

### **Principles of Money, Banking, and Financial Markets**

**LAWRENCE S. RITTER & WILLIAM L. SILBER**

Ritter and Silber has been widely praised as the most complete, literate, and scholarly introduction to the field of money, banking, and financial markets available. Guided by 200 questionnaire responses from instructors, the Fourth Edition has been thoroughly revised and reorganized to incorporate the most up-to-date material. Augmented by extensive illustrative material, the book provides full, balanced coverage of all the topics dealt with in standard money and banking courses. Text, \$25.95 Instructor's Manual, gratis Study Guide, \$10.00

### **The Ideal Worlds of Economics**

**BENJAMIN WARD**

Is there only one "true" way of understanding the economic universe in which we live? In this book, a distinguished economist demonstrates that there are in fact *three* distinct ways of describing how economies work—a liberal way, a radical way, and a conservative way—each consistent with presently available evidence and each in harmony with widely held moral views. Indeed, he presents these "optimal economic world views" so persuasively that the reader will find himself fully convinced by each—until he comes to the next.

Now available in its entirety, paper, \$18.00

### **Losing Ground**

**American Social Policy 1950–1980**

**CHARLES MURRAY**

"The Administration's new 'bible.'"—LEONARD SILK, *The New York Times*. "A great book. . . . The first important 'third generation' critique of recent social policy."—*The Wall Street Journal*. "The great value of *Losing Ground* is that, without bile and without rhetoric, it lays out a stark truth that must be faced: two decades of well-meaning programs to erase racism and poverty in the U.S. have left those at the very bottom of the ladder worse off than ever."—*Business Week*.

\$23.95

## Misregulating Television

*Network Dominance and the FCC*

**Stanley M. Besen,  
Thomas G. Krattenmaker,  
A. Richard Metzger, Jr.,  
and John R. Woodbury**

This book provides evidence that it is the FCC regulations — rather than the networks — that have been principally responsible for shaping and limiting the viewing options of the public. The authors argue that, by standards of competition, programming diversity, and localism, the restraints that the FCC has tried to impose have been either ineffective or harmful.

**Cloth \$24.00 208 pages**

## The Soul of Modern Economic Man

*Ideas of Self-Interest,  
Thomas Hobbes to Adam Smith*  
**Milton L. Myers**

"Milton Myers deserves congratulations for producing this concise, insightful, and highly readable account of the intellectual origins of capitalist economics." — *The Annals of the American Academy of Political and Social Science*

**Paper \$6.95 158 pages**

## Macroeconomics and Micropolitics

*The Electoral Effects of Economic Issues*  
**D. Roderick Kiewiet**

Kiewiet systematically investigates the influence of economic concerns — particularly inflation and unemployment — on voting decisions in national elections.

"This is an important book. . . . Scholars and budding scholars in political science, economics, and sociology will find it indispensable." — Richard Brody, Stanford University

**Paper \$5.00 186 pages**

## New Studies

*In Philosophy, Politics,  
Economics, and the History of Ideas*  
**Friedrich A. Hayek**

This selection of Hayek's recent essays and lectures includes several important ones that have never before been published in English. The essays cover a wide range of subjects but are united by a common philosophical approach. Included are Hayek's contributions to the debate on inflation, a historical and systematic account of liberalism, and the Nobel Memorial Lecture delivered in Stockholm in 1974, when Hayek was awarded the Nobel Prize in Economic Science.

**Paper \$12.50 322 pages**

## Anticipations of the General Theory? And Other Essays on Keynes

**Don Patinkin**

Patinkin examines the much-debated question of whether Maynard Keynes' greatest work — *The General Theory of Employment, Interest, and Money* — was an instance of simultaneous discovery.

"This is a book to enjoy — there are no loose ends, no undocumented details, no casual references. The research is precise, detailed, confident and competent."

— *Wall Street Review of Books*

**Paper \$10.00 304 pages**

## Selfishness, Altruism, and Rationality

*A Theory of Social Choice*  
**Howard Margolis**

"Howard Margolis's intriguing ideas . . . provide an alternative to the crude models of rational choice that have dominated economics and political science for too long."

— *Times Literary Supplement*

**Paper \$8.00 206 pages**

The University of **CHICAGO** Press

5801 South Ellis Avenue, Chicago, IL 60637

## *Economics from MIT*

### **Market Structure and Foreign Trade:**

Increasing Returns, Imperfect Competition, and the International Economy

*Elhanan Helpman and Paul R. Krugman*

Relating current theoretical work to the main body of trade theory, this book offers entirely new material on contestable markets, oligopolies, welfare, and multinational corporations, and offers new insights on external economies, intermediate inputs, and trade composition. \$22.50

### **Exchange Rate Management under Uncertainty**

*edited by Jagdeep S. Bhandari*

*Foreword by Richard N. Cooper*

This collection of original work explores issues at the frontiers of exchange rate determination and open economy macroeconomics. \$30.00

### **Monetary Policy in Our Times**

*edited by Albert Ando, Hidekazu Eguchi,  
Roger Farmer, and Yoshio Suzuki*

These eight essays cover monetary policy in an uncertain world, domestic and international aspects of monetary policy, and policies to overcome stagflation. In particular, they recognize and provide a lively forum for the different views of academic and central bank economists. \$25.00

### **Equilibrium and Macroeconomics**

*Frank Hahn*

This book collects Frank Hahn's less technical essays on economic theory. With his characteristic style, wit, and principle he explores the concept of equilibrium and its "usefulness," the problematic role of money in the general equilibrium framework, and the shortcomings of monetarists, rational expectationists, and neo-Ricardians. \$29.95

*Now available in paperback*

### **Money and Inflation**

*Frank Hahn*

This rigorous essay in abstract theory is also a sustained and brilliant assault on the new monetarism. \$5.95

### **Trade Policy in the 1980s**

*edited by William R. Cline*

These twenty-two contributions by many of the top scholars in the field cover a broad range of important areas of trade conflict. "...contains ideas and data that will be relevant for some time to come."—*Foreign Affairs*  
Institute for International Economics. \$15.00

*Write for our current economics catalog*

**The MIT Press**

28 Carleton Street, Cambridge, MA 02142

## **Worker Cooperatives in America**

**Edited by ROBERT JACKALL and HENRY M. LEVIN**

This comprehensive study of a vital form of workplace democracy examines the history, dynamics, challenges, and potential of worker cooperatives in America. It illuminates key aspects of the cooperative phenomenon and lays the groundwork for future research.

\$24.95

## **The Suburban Squeeze**

**Land Conversion and Regulation in the San Francisco Bay Area**

**BY DAVID E. DOWALL**

While the tension between housing demand and land use control is felt across the U.S., the problems posed by local land use controls and state environmental regulations are most acute in California. Dowall focuses on the effects of land use and environmental regulations in San Francisco Bay Area communities, providing insights into the dynamics of land use regulation in any highly regulated market. *California Series in Real Estate Economics and Finance* and *California Series in Urban Development*. \$24.50

## **Latin Journey**

**Cuban and Mexican Immigrants in the United States**

**by ALEJANDRO PORTES and ROBERT L. BACH**

This volume details an eight-year survey of Mexican and Cuban immigrants in the 1970s. The authors describe patterns of occupational and economic development, cultural adaptation, and social relationships both within the ethnic circle and in the larger community. \$45.00 cloth, \$11.95 paperback

## **The Reconstruction of Western Europe**

**1945-1951**

**by ALAN S. MILWARD**

A comprehensive study of the economic and political reconstruction of western Europe since 1945, by one of the foremost historians on the subject. Milward offers strikingly new interpretations within a truly major work of scholarship. \$38.50

## **The Economic Rise of the Habsburg Empire**

**1750-1914**

**by DAVID F. GOOD**

Little is known about the economic history of the Habsburg Empire. In this survey of economic development in the late stages of one of Europe's former great powers, Good provides overwhelming evidence that the Habsburg Empire's economy did not fail in its last one hundred years. \$32.00

## **Chinese Business Under Socialism**

**The Politics of Domestic Commerce, 1949-1980**

**by DOROTHY J. SOLINGER**

Focusing on three determinants of commercial policy in China—the planned economy, policy conflict among the leadership, and economic underdevelopment—Solinger looks at how the Chinese have organized the balance between public and private sectors in handling the treatment of the private sector, the disposal of consumer goods, and free markets for agricultural produce. \$30.00

## **Fathers Work for Their Sons**

**Accumulation, Mobility and Class Formation**

**in an Extended Yoruba Community**

**by SARA S. BERRY**

In this original study of Yorùbá cocoa farmers and their descendants in western Nigeria, Berry examines the consequences of agricultural commercialization of economic development, political mobilization, and social change. \$24.50

## **NEW FROM 21ST CENTURY PRESS**

### ***International Trade and the Future of the West***

**John M. Culbertson**

Recent events show that the shift of industries and jobs between nations depends on *absolute* cost—not *comparative advantage*. This book demonstrates that the straightforward use of economic analysis explains these events, and that the tools of economics have been widely misused in support of “free trade.”

In the radically new situation that now exists, “free trade” causes international wage-competition and the shift of industries and jobs from high-wage to low-wage nations. This process threatens an economic fall of the West. It will make for world-wide poverty in a world in which the burden of the massive and worsening overpopulation of some countries is spread through wage-competition to all.

To escape this destructive process and bring about trade that actually benefits the participating nations requires not “free trade” but trade that is managed so as to be in balance—the condition that is required to make comparative advantage applicable—and to lead to a justifiable distribution of industries among nations. This book raises fundamental issues for introductory students and students of international trade. It permits critical consideration of the relation between recent events and traditional textbook doctrines on international trade.

242 pages    hardback    1984    \$17.95 (plus \$1.50 shipping)  
paperback    1985    \$8.95; at faculty discount, \$7.15; examination copy, \$5.35  
(each plus \$1.20 shipping and handling)

### ***The Dangers of “Free Trade”***

**John M. Culbertson**

This booklet gives a brief statement of the new interpretation of international trade of *International Trade and the Future of the West*. It is suitable as a supplementary text or partial text in introductory as well as advanced courses. It will serve to open up discussion of the revolutionary changes in international trade, the way economic analysis is to be applied to them, and the effects that will follow from different kinds of trade policies.

### ***Competition, Constructive and Destructive***

**John M. Culbertson**

“Competition” is depicted by economic theory and the current deregulation doctrine as inherently beneficial—so that what the economy needs is only *more “competition.”* But experience and much of the literature of economics imply that “competition” is not necessarily beneficial, its effects depending on what firms *are competing at*. In this view, to achieve constructive competition requires judicious rules and regulations, which will prevent the destructive competition that otherwise will prevail.

This booklet will enlarge and enliven discussion in introductory and advanced courses. It provides a basis for considering controversial issues in the application of economic analysis to current cases of economic regulation and deregulation.

both about 40 pages    paperback    1985  
\$2.95; at faculty discount, \$2.35; examination copy, \$1.80  
(each plus \$.80 shipping and handling)

## ECONOMETRIC SOFTWARE FROM TSP

**TSP™ 4.0** : a greatly enhanced edition of the Time Series Processor software package, in use at over 650 sites worldwide. The new release features

- Convenient data manipulation for time series and cross section data; full missing value capabilities.
- All standard econometric techniques, ordinary least squares, two and three-stage least squares, polynomial distributed lags, autoregressive correction.
- Nonlinear estimation for single and multi-equation models.
- Forecasting and solution of simultaneous models.
- Box-Jenkins identification, estimation, and forecasting.
- Databank facility for IBM, Vax, Prime, and Univac computers.
- Many other features such as matrix algebra which makes TSP a complete programming language for econometric problems.

**RATS** : a complete package for vector autoregressive models of time series, written by Litterman and Doan of VAR Econometrics. It features the estimation and simulation of VAR and ARIMA models, as well as a powerful set of spectral analysis techniques.

**PROBIT** : for the binary probit model.

**MLOGIT** : for the multinomial or conditional logit model.

**TSP International** 928 Mears Court, Stanford, CA 94305, (415) 326-1927

### KING SAUD UNIVERSITY Riyadh, Saudi Arabia

The College of Administrative Sciences, King Saud University, has vacant faculty positions (Professor, Associate Professor, Assistant Professor) for Ph.D. holders, who would be employed on contract basis as of commencement of the academic year 1985-1986, which begins on July 27, 1985.

The language of instruction at the college is ARABIC except for the Hospital Administration Program. The college has the following academic departments: (1) Accounting, (2) Business Administration, (3) Economics, (4) Law, (5) Political Science, (6) Public Administration, (7) Quantitative Methods, and (8) Hospital Administration, which is a part of the Department of Public Administration.

**Noteworthy benefits:**

- Free return air tickets annually for faculty member and his family.
- Furnished accommodation or housing and furnishing allowances.
- Monthly transport allowance.
- Relocation allowance.
- End-of-service gratuity.
- Free medical and dental care covering family.
- Contribution by University to tuition fees of non-Arabic-speaking children.

Interested academicians are kindly requested to send non-returnable photocopies of their academic diplomas and specialized experience certificates, together with their resumes (including lists of their publications and references) and written applications indicating the position applied for and the subjects the applicant is qualified to teach, to:

Dean of College  
King Saud University  
P.O. Box 2459  
Riyadh 11451, Saudi Arabia

and

Ms. Aida Ganim  
King Saud University Office  
2425 West Loop South, Suite 450  
Houston, TX 77027

Please include address and telephone number (if available) so, if selected, you may be contacted.

## **The Economics of Unemployment**

### ***A Comparative Analysis of Britain and the United States***

**JAMES J. HUGHES and RICHARD PERLMAN**

In this comprehensive treatment of the issues and problems of unemployment, the authors integrate discussions of measurement, theory, and policy with empirical evidence drawn from postwar experience in the United States and the United Kingdom.

Cloth \$39.50 Paper \$12.95

## **The Economist's View of the World**

### ***Governments, Markets, and Public Policy***

**STEVEN E. RHOADS**

In a clear, lively, and nontechnical style, the author explains and assesses the way in which economists view the world of public policy. The book explains why Democratic and Republican economists so often agree about micro-policy issues, and why they are frequently at odds with many politicians, consumer advocates and business and union leaders.

"I have been bowled over by the eloquence and incisiveness of the argument in the critical chapter on 'The Economist's Consumer and Individual Well Being' . . . the author shows such a clear understanding of the economist's emphasis on opportunity cost, on benefit cost comparisons, and the like."—Alfred E. Kahn, Professor of Economics, Cornell University

"I doubt that there is a better book for the typical person interested in improving his or her ability to think clearly about public policy issues."—Edgar O. Olsen, Professor of Economics, University of Virginia

Cloth about \$37.50 Paper about \$12.95

## **Energy Policy in America Since 1945**

### ***A Study of Business-Government Relations***

**RICHARD H.K. VIETOR**

Since the development of a sound energy policy for cheap fossil fuel—coal, petroleum, and gas—has become a central concern in shaping the economy, we have needed a balanced, authoritative account of the history of energy policy in the US, which, at last, we have in Richard Vietor's book.

"This book should be read by anyone who is interested in energy policy, business history, or business-government relations—which means everyone."—Robert B. Stobaugh, Director of The Energy Project, Harvard Business School

*Studies in Economic History and Policy:*

*The United States in the Twentieth Century*

\$29.95

## **Money and Markets**

### ***Essays by Robert W. Clower***

**DONALD A. WALKER, Editor**

Robert Clower's essays, brought together by Donald Walker, constitute a well-rounded treatment of the major problems in monetary economics, and the volume as a whole demonstrates how the study of monetary economics may extend current knowledge of the short-run economic fluctuations and prove useful in developing policy options to ameliorate them.

\$37.50

**Cambridge  
University  
Press**

## **Drastic Measures**

### ***A History of Wage and Price Controls in the United States***

**HUGH ROCKOFF**

A history of America's use of wage and price controls from colonial times through Richard Nixon's experiment with controls which began in 1971. Rockoff concludes that temporary controls may serve as useful "pain-killers" that permit more fundamental cures, such as restrictive monetary and fiscal policies, to be used to maximum effect.

*Studies in Economic History and Policy:  
The United States in the Twentieth Century*

\$29.95

## **Monetary Politics**

### ***The Federal Reserve and the Politics of Monetary Policy***

**JOHN T. WOOLLEY**

"... a technically proficient analysis of a highly complex area of public policy written in an uncommonly lively and stylistically attractive way. Woolley's grace as a writer makes the intricacies of monetary policy accessible to non-specialists and reflects the drama and significance inherent, but rarely revealed, in a subject usually regarded as esoteric."—*Congressional Quarterly Weekly Report*

"Woolley's study is a refreshing alternative to both the short-term preoccupations with market movements and the trivialisation of the analysis of political influences ... a scholarly study, well documented at every point. ... essential reading for anyone who wants to understand monetary policy making in the United States."—*The Banker*

\$37.50

## **Game Theoretic Analysis of Voting in Committees**

**BEZALEL PELEG**

A theoretical and completely rigorous analysis of voting in committees that provides mathematical proof of the existence of democratic voting systems which are immune to the manipulation of preferences of coalitions of voters.

*Econometric Society Monographs in Pure Theory*

\$37.50

## **Instrumental Variables**

**R.J. BOWDEN and D.A. TURKINGTON**

The authors present and develop the methodology of instrumental variables in its most general and explanatory form. They clearly illustrate these instrumental variables techniques and apply them to a range of problems, both linear and nonlinear.

*Econometric Society Monographs in Quantitative Economics*

\$34.50

## **Rivalry and Central Planning**

### ***The Socialist Calculation Debate***

**DON LAVOIE**

Professor Lavoie offers a serious challenge to conventional thinking in contemporary comparative systems and the economics of socialism. He argues that the lessons of the socialist calculation debate is that planning and markets are fundamentally alternative coordination mechanisms.

*Historical Perspectives on Modern Economics*

About \$34.50

All prices subject to change. Order from your bookstore or call our Customer Service Department at 1-800-431-1580 (outside New York State and Canada). MasterCard or Visa accepted.

**Cambridge University Press, 32 East 57th Street, New York, NY 10022**

The American Economics Association (AEA) is now soliciting applications to host the AEA Summer Program for Minority Students, for three summers beginning in 1986.

This program is now in its twelfth year and is currently at the University of Wisconsin at Madison. Previous host institutions have been Berkeley, Northwestern, and Yale.

The intent of the program is to increase the number of Blacks, Hispanics, and Native Americans pursuing the Ph.D. in Economics. In recent years the course of study has been an intensive eight to ten week program in intermediate microeconomics and macroeconomics, at the honor's level, and courses in econometrics or mathematical economics.

Funding for the program has been provided by the hosting institutions and grants to the AEA. Applications should be sent to Professor Donald J. Brown, chairman of the AEA Committee on the Status of Minority Groups in the Economics Profession, CSMGEP, no later than September 1, 1985.

# In all probability, you'll be hearing a lot about this new Wadsworth text...

**BASIC STATISTICS IN BUSINESS AND ECONOMICS, 4th Edition**  
George W. Summers, Arizona State University; William S. Peters, University of New Mexico; and Charles P. Armstrong, University of Rhode Island

**H**ere is an outstanding text by authors who, as teachers, know the difference between a basic text that is adequate and one that is outstanding. This new edition builds on the strengths of previous editions in *all* areas:

**1** *Aptness of examples and exercises.* The text's applied flavor links the realistic business situations in the text to the many examples and the carefully graded problems.

**2** *Emphasis on logical thinking.* This edition clarifies and expands coverage on hypothesis testing and two-way ANOVA, and focuses even more strongly on an intuitive approach to concepts, without resorting to rigorous mathematics.

**3** *Abundant practice materials.* Data sets and computer problems are greatly expanded in this edition, giving students ample chances to fix ideas and procedures.

**4** *A solid support system.* The Student Supplement, prepared by the authors, provides programmed learning units, diagnostic self-tests, self-correcting exercises, and achievement tests. Approximately 768 pages. 7-3/8 x 9-1/4. Casebound. October 1984. © 1985. Student Study Guide. Instructor's Manual.

# **ADAM SMITH REFERENCES TO THE WEALTH OF NATIONS**

Pergamon Press has compiled the complete texts of monographs used by Adam Smith as references for *The Wealth of Nations* and put them on microfiche. Part of a new Pergamon series, *History of Economics*, this major collection goes beyond Edwin Cannan's classic *Index of Authorities*.

Published in two segments, and now available for immediate delivery, this comprehensive collection comprises:

- **Over 2000 Fiche**
- **Over 180,000 Filmed Pages**
- **Two Important Supplementary Collections**
  - 46 works from Adam Smith's personal library
  - 22 early editions of *The Wealth of Nations*

## **WORLD TRADE AND PAYMENTS**

### **An Introduction**

*Fourth Edition*

**Richard E. Caves and Ronald W. Jones**

Thoroughly updated, this revision of the leading text for international economics features a reworked, up-to-date treatment of trade theory and strengthened coverage of international finance. And this clear, modern account is now more useful than ever — with supportive chapter-ending exercises and problems new to this edition.

#132276/cloth/544 pages

*New!*

## **MANAGERIAL ECONOMICS**

**Robert F. Rooney**

This comprehensive new text is more than merely a price theory text disguised as a managerial economics text. Rooney's fresh approach presents microeconomics in a more useful way for business students. The text features worked-out cases that show students how theory can be applied to practical business decisions and problems. Calculus is used where appropriate, and numerous problems are included at the end of each chapter.

#755966/cloth/500 pages/with Instructor's Manual

*Highly successful!*

## **MACROECONOMICS**

*Third Edition*

**Robert J. Gordon**

Users across the nation agree that Gordon's Third Edition is the best text — with the best package — for the intermediate macro course. Simplified presentation of inflation and unemployment as well as the latest data available enhance this widely-used text's superb integration of modern theory with numerous real-world cases.

*The eighth—and election year—edition  
of the highly successful reader!*

**“An excellent book of supplemental readings  
for an introductory macroeconomics course.  
The articles are more current and politically  
diverse than most readings in the field.”  
—AAAS Science Books & Films**

# **INTRODUCTORY MACROECONOMICS 1984–85**

## **Readings on Contemporary Issues**

Edited by PETER D. McCLELLAND

The eighth in a series of highly successful and widely adopted annual readers for all introductory economics courses, *Introductory Macroeconomics 1984–85* contains more than fifty articles by leading economists published in periodicals as recently as May 1984. The articles are chosen to reflect the entire spectrum of economic opinion, from left-wing to right-wing, from liberal to conservative, from Keynesian to monetarist to supply-side advocate. Writers featured in this past year's reader included well-known commentators on macroeconomic problems such as Kenneth Arrow, Barbara R. Bergmann, Karl Brunner, Milton Friedman, Henry A. Kissinger, Joseph A. Pechman, Paul Craig Roberts, Paul Samuelson, David A. Stockman, and Paul A. Volcker.

The provocative articles and essays are selected from a diverse range of popular and scholarly sources, including *The Wall Street Journal*, *The Economist*, *Time*, *The Progressive*, *Dollars & Sense*, *New Republic*, *Economic Outlook USA*, *The New York Times*, *Challenge*, *U.S. News & World Report*, *Society*, *Newsweek*, Federal Reserve publications, and other major magazines and journals. The issues covered in *Introductory Macroeconomics 1984–85* include: inflation and unemployment, monetary and fiscal policy, institutional changes in money and banking, the growing federal deficit and proposals to reduce it, tax-based incomes policy, economic growth and reindustrialization, and poverty, welfare, and income distribution. **\$9.95 softcover**

**Free Market Economics**  
**A CRITICAL APPRAISAL**

ANDREW SCHOTTER, New York University

A careful analysis of the free-market economics argument, this book defines the basic assumptions of the argument and identifies their roots in the history of economic thought. Schotter reviews the major criticisms of the argument and raises some serious doubts about the blind advocacy of free market solutions to current social problems.

Paperbound. 147 pages.  
Just Published

**The Politics of International  
Economic Relations**  
**Third Edition**

JOAN EDELMAN SPERO, Senior Vice  
President, American Express Company

A clearly written, carefully focused examination of the political dynamics of international economics, this book addresses all the major topics of concern in the field, including money, trade, multinational corporations, North-South relations, economic aid, and oil. This Third Edition provides new or expanded coverage of such important topics as protectionism, the declining power of OPEC, the consequences of Third World debt, and the impact of high U.S. interest rates and the overvalued dollar. A glossary of key economic terms is now included at the back of the book.

Paperbound. 400 pages (probable).  
February 1985

**The Contemporary  
International Economy**  
**A READER**

**Second Edition**

JOHN ADAMS, University of Maryland,  
College Park

Intended as a supplement for courses in international economics and business, this book brings together 33 readings on the major issues in international economics today. The book provides a broad range of viewpoints, with selections by such noted economists as Martin Feldstein, Robert Baldwin, Herbert Grubel, Mordechai Kreinin, and Peter Drucker. The book is fully up to date: all but four of the readings are new to this edition.

Paperbound. 550 pages (probable).  
February 1985

# Oxford

## Order and Conflict in Contemporary Capitalism

**Studies in the Political Economy of Western European Nations**

Edited by JOHN H. GOLDTHORPE, *Nuffield College, Oxford*. This comparative anthology examines the methods used by Western countries to manage political conflict over the distribution of economic and social resources since 1945. Bringing together major studies by leading economists, political scientists, sociologists, and historians, the collection offers a new basis for assessing the relative merits and weaknesses of corporatist and other settlement strategies.

1985 352 pp. cloth \$34.95 paper \$15.95

## The Way People Work

**Job Satisfaction and Customer Service**

CHRISTINE HOWARTH. What makes a job satisfying? Does greater job satisfaction lead to increased efficiency and, if so, is the extra cost worthwhile? How can managers and employees improve the quality of working life? Using detailed case studies of various American and European organizations, this practical guide explains how workplaces can be personally—and economically—rewarding for managers and employees alike.

1984 224 pp. \$23.95

## The Co-operative Game Theory of the Firm

MASAHIKO AOKI, *Institute of Economics, Kyoto University, Japan, and Stanford University*. This highly original work challenges the widely-held view of the firm as a mysterious "black box," operating solely to maximize profit for the shareholders. Instead, Aoki proposes an entirely new economic model in which the ideal firm is a coalition of shareholders and employees, with its market behavior and internal distribution the result of co-operative bargaining.

1985 288 pp.; 9 figs. \$29.95

## Putting People First

**Sociological Dimensions of Rural Development**

Edited by MICHAEL M. CERNEA. This useful anthology addresses the social and practical considerations involved in the design and implementation of effective rural development projects. The contributors, studying topics ranging from the social organization of the productive system to the role of the World Bank, provide solid advice and recommendations for incorporating regional sociological factors into the design of any successful development project. (*A World Bank Publication*)

1985 400 pp. \$24.95

## Winners and Losers in Colombia's Economic Growth of the 1970s

MIGUEL URRUTIA, *United Nations University, Tokyo*. Most experts believe that Colombia's economic growth during the 1970s did not improve the distribution of income. Here, Urrutia draws on a wide array of statistical data to reach a different conclusion: that income distribution during this period did not, in fact, deteriorate and that the real incomes of the poorest workers actually improved markedly. (*A World Bank Publication*)

1985 160 pp. \$19.95

## Input-Output Economics

*Second Edition*

WASSILY LEONTIEF, *Institute for Economic Analysis, New York University*. In 1966, Wassily Leontief was awarded the Nobel Prize for his model of Input-Output economics. This collection of papers provides the only comprehensive introduction to the model he has written, and is now thoroughly revised—12 of the 18 papers are new to this edition. The book begins with non-technical articles on the theory of Input-Output economics and progresses to more technical discussions and then to specific applications of the theory.

May 1985 320 pp.; illus. cloth \$29.95 paper \$14.95

## Leading Issues in Economic Development

*Fourth Edition*

GERALD M. MEIER, *Stanford University*. Completely revised and updated to reflect the current mood of stock taking and reassessment, this unique book brings order to the diffuse subject of economic development while maintaining a variety of viewpoints and different perspectives. The author uses a broad range of theoretical, applied, and policy materials in emphasizing the strategic policy issues which accelerate the development of Third World nations.

1984 768 pp.; 45 illus. paper \$19.95

## The World Crisis in Education

*The View From the Eighties*

PHILIP H. COOMBS, *International Council for Educational Development*. In this sequel to his highly acclaimed book, *The World Educational Crisis*, Philip Coombs identifies significant educational trends that have developed over the past 20 years and examines critical future issues destined to confront all nations, with varying intensity, over the next 15 years. Possible ways of coping with these issues are explored through educational reforms, innovations, and new forms of international cooperation.

1985 384 pp.; 25 illus. cloth \$24.95 paper \$10.95

## Taxation for Development

*Principles and Applications*

STEPHEN R. LEWIS, *Williams College*. This introduction to the analysis of tax policy in developing countries focuses on open economies and the ways in which openness to international trade and to movements of capital and skilled labor influence the scope for, and the effects of, tax policy. More than 50 policy problems—based on actual case studies from a variety of countries—allow the reader to apply principles developed in theory to actual tax policy issues.

1985 256 pp.; illus. cloth \$29.95 paper \$12.95

## Econometric/Statistical Package

# xSTAT™

### Mainframe Capability, Accuracy and Speed for Your IBM Personal Computer

---

**xSTAT:****A Reliable, Economical Alternative to Mainframe Computing**

---

- Is designed for the analysis of **VERY LARGE** as well as small data sets. It has no limit on sample size (total number of observations); and allows up to 50 variables per regression.
- Can generate and save an **X'X product matrix** the first time a data set is used. Subsequent regressions can be made from it to eliminate repetitive readings of input data normally required in statistical packages—very time-consuming when disk inputs are involved.
- Supports Intel 8087 80-bit Math Co-processor for **FAST NUMBER CRUNCHINGS** (has software emulation for systems without the co-processor to attain same accuracy). Double precision is used in matrix operations.
- Produces estimated coefficients that are identical to mainframe TSP results to four significant digits.
- Executes at **HIGH SPEED** when an **X'X matrix** is used to estimate regressions even for very large samples—it takes only seconds to complete a run.
- The output can be directed to disk, printer or screen. The display can be 132 or 80 columns wide and the statistics and coefficients can be printed in F-format (e.g., 123.456) or E-format (1.23456 + E02).
- Works in either batch or prompt mode; requires no special command language. **EASY TO USE.**

#### THE PACKAGE INCLUDES:

##### Data Reformatting and Transformation Program

- Converts formatted data into unformatted data and vice versa; aggregates over records; merges files; accepts data downloaded from mainframe or generated by other programs including Lotus 1-2-3, Visicalc, dBase II, WordStar, other word processors and editors.
- Allows selection of subsamples based on value range or sequential order. Converts fractions to decimal numbers (e.g., stock quotes,  $32\frac{1}{8} = > 32.125$ ).
- Has 14 mathematical/logical transformation functions for vector multiplication, division, addition, subtraction, logarithm, exponent, lagged variables, first difference, dummy variables, and time trend.

##### Descriptive Statistics

- Minimum, maximum, mean, standard deviation, sum of squares, correlation coefficients, **CROSSTABS**, etc.

##### Ordinary Least Squares (Multiple regressions) and Two-stage Least Squares

- Generates variance/covariance matrix of coefficients, standard error, t-statistic, R-square, adjusted R-square, Durbin-Watson statistic and F-statistic. Calculates predicted values, residuals, and produces residual plot.
- Allows subsample selection; can also estimate regressions from product moment matrix (contingency table).

##### Pooling Cross-Section and Time-Series Data

- Estimates regressions for samples with multi-period observations (e.g., panel study). Automatic stacking of data matrix (diagonal block matrix). Estimates coefficients and F-statistics for testing various hypotheses of (1) a common intercept and slope; (2) a common slope and different intercepts; (3) a common intercept and different slopes; (4) different intercepts and different slopes.

#### SYSTEM REQUIREMENTS

**IBM PERSONAL COMPUTER** (PC or XT), COMPAQ or IBM PC compatible systems: 1 floppy disk drive or a hard disk system; DOS 1.1 or 2.0 and 192K memory.

**PRICE:** \$250 for the complete package. (Accept checks, Visa & MasterCard. Or order through your local dealer.)

#### RELATED PRODUCT

Spreadsheet Forecasting Templates for Lotus 1-2-3: reads the estimated coefficients and inverse **X'X** matrix, saved optionally by xSTAT, directly into 1-2-3 for making "what if" forecasts and producing graphs. No keyboard data entry is needed. The templates are imbedded with formulae for estimating the standard error and confidence interval for the forecasted dependent variable that changes as the forecasted independent variables are varied. **PRICE \$100**

# CSWEP

*The Committee on the Status of Women in the Economics Profession*

**CSWEP**, an arm of the American Economic Association, publishes a thrice-yearly newsletter to let you know all the news - good or bad - about women in the economics profession.

The newsletter carries items about:

*research on sex role issues*

*new publications*

*hiring (or non-hiring) of women economists*

*conferences for or about women*

*what other professional women's groups are doing to  
further women's interests in their disciplines*

*developments in government and industry*

**CSWEP** speaks up on behalf of women economists in hiring, research and governmental policies.

**CSWEP** represents women's point of view in the committee work of the American Economic Association. It makes an annual report to AEA on the status of women economists.

**CSWEP** is a presence at annual meetings of the AEA and of the regional economics associations. It sponsors sessions at these meetings, where research by and about women can get an audience.

**CSWEP** publishes a **ROSTER OF WOMEN ECONOMISTS** for purposes of communication and job placement. Dues-paying members receive the latest roster, which lists women economists by and where they teach or work, by their specialty in economics, and by city, as well as alphabetically.

**CSWEP** is the voice of women economists when coalitions of professional women join to advance sex equality in professional life.

To become a dues-paying member of **CSWEP**  
send this with a check for \$15 (tax deductible) made out to **CSWEP** to:  
**CSWEP**, 3065 Fermanagh Dr., Tallahassee, FL 32308

# A New Standard Of Excellence

**MACROECONOMICS: The Dynamics Of Theory And Policy—  
an exciting and successful new text by William J. Boyes:**

- Provides a clear integration of macro theory and policies within the historical context of their development
- Progresses rapidly to a development of the Aggregate Demand/Aggregate Supply framework and then uses it to unify the treatment of theory
- Devotes an entire chapter to an examination of alternative expectations schemes—including rational and adaptive expectations models
- Applies the unifying AD/AS Model to examine such current issues as tax policy, budgets and deficits, Social Security, declining productivity growth, the political business cycle, and the Third World Debt
- Presents a balanced treatment of current controversies—including rules versus discretion, the explanation of stagflation, contract- and information-based theories of the business cycle, and supply-side economics

**MATHEMATICAL AND STATISTICAL PROGRAMMING PACKAGE FOR YOUR IBM PC**  
FAST • EASY TO USE • POWERFUL

# GAUSS™

**YOU'VE NEVER SEEN ANYTHING LIKE IT!**

**GAUSS** is a sophisticated mathematical and statistical programming package for the IBM PC and compatibles. It combines speed, power, and ease of use in one amazing program.

**GAUSS** allows you to do essentially anything you can do with a mainframe statistical package — and a lot more.

Personal computers are friendly, convenient, and inexpensive. So is **GAUSS**. **GAUSS** is not just a stripped-down mainframe program. **GAUSS** has been designed from the ground up to take advantage of all of the conveniences of a personal computer. After trying **GAUSS**, you may never use a mainframe again.

**GAUSS** comes with programs written in its matrix programming language that allow you to do most econometric procedures, including OLS, 2SLS, 3SLS, PROBIT, LOGIT, MAXIMUM LIKELIHOOD, and NON-LINEAR LEAST SQUARES.

In the current version, **GAUSS** will accept up to 90 variables in a regression. There is no limit on the number of observations.

**GAUSS** will do a regression with 10 independent variables and 800 observations in under 4 seconds — and with 50 variables and 10,000 observations in under 18 minutes. It will compute the maximum likelihood estimates of a binary logit model, with 10 variables and 1,000 observations, in 1-2 minutes, depending upon the number of iterations required.

**GAUSS** allows you to do complicated statistical procedures that you would never imagine trying on a mainframe. It is easy to program almost any routine, and **GAUSS** is so fast that it can do almost any job. But the nicest thing of all is that the cost of time on your personal computer is essentially zero!

**GAUSS** is an excellent teaching tool. It makes programming easy and allows students to focus on concepts and techniques.

If you can write it mathematically, you can write it in **GAUSS**. Furthermore, you can write it in **GAUSS** almost exactly the way you would write it mathematically.

**GAUSS** is 10-15 times faster than other programs that use the 8087, and 15-100 times faster than other programs that do not use the 8087.

As in APL, single statements in **GAUSS** can accomplish what might take dozens of lines in another language. However, **GAUSS** provides you with additional powerful numerical operators and functions — especially for statistics and the solution of linear equations — that are not found in APL. And, of course, the syntax in **GAUSS** is much more natural (for most of us) than that in APL.

**GAUSS** has state-of-the-art numerical routines and random number generators.

**GAUSS** is extremely accurate. It allows you to do an entire regression in 19 digit accuracy. It will compute the Longley benchmark coefficients in 5 hundredths of a second with an average of 11 correct digits! (Try that on a mainframe!)

**GAUSS**, with its built-in random number generators and powerful functions and operators, is an excellent tool for doing simulations.

## **GAUSS and the 8087 NUMERIC DATA PROCESSOR GIVE YOU MINICOMPUTER PERFORMANCE ON YOUR DESKTOP.**

### **SPECIAL INTRODUCTORY OFFER**

With 30 Day Money

Back Guarantee ..... Reg. 395.00 **\$250.00**

**GAUSS** requires an IBM PC with at least 256K RAM, an 8087 NDP, 1 DS/DD disk drive, DOS 2.0 (or above).

# The American Economic Review

## PAPERS AND PROCEEDINGS

OF THE

Ninety-Seventh Annual Meeting

OF THE

AMERICAN ECONOMIC ASSOCIATION

Dallas, Texas, December 28-30, 1984

Program Arranged by Charles P. Kindleberger

Papers and Proceedings Edited by John G. Riley and Wilma St. John

MAY 1985

# THE AMERICAN ECONOMIC ASSOCIATION

●Published at George Banta Co., Inc., Menasha, Wisconsin. The publication number is ISSN 0002-8282.

●*THE AMERICAN ECONOMIC REVIEW* including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and *Supplements*, is published by the American Economic Association and is sent to all members five times a year: March; May; June; September; December.

Regular member dues for 1985, which include a subscription to both the *American Economic Review* and the *Journal of Economic Literature* are as follows:

- \$35.00 if annual income is \$30,000 or less;
- \$42.00 if annual income is above \$30,000, but no more than \$40,000;
- \$49.00 if annual income is above \$40,000.

Nonmember subscriptions will be accepted only for both journals: Institutions (libraries, firms, etc.), \$100 a year; individuals, \$65.00. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

In countries other than the United States, add \$11.00 to the annual rates above to cover extra postage.

●Correspondence relating to the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinshaw, 1313 21st Avenue So., Suite 809, Nashville, TN 37212-2786. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

●Second-class postage paid at Nashville, Tennessee and at additional mailing offices, Printed in U.S.A.

●Postmaster: Send address changes to *American Economic Review*, 1313 21st Avenue So., Suite 809, Nashville, TN 37212-2786.

Founded in 1885

THE purpose of the American Economic Association, according to its charter, is the encouragement of economic research, the issue of publications on economic subjects, and the encouragement of perfect freedom of economic discussion. The Association as such takes no partisan attitude, nor does it commit its members to any position on practical economic questions. It is the organ of no party, sect, or institution. People of all shades of economic opinion are found among its members, and widely different issues are given a hearing in its annual meetings and through its publications. The Association, therefore, assumes no responsibility for the opinions expressed by those who participate in its meetings. Moreover, the papers presented are the personal opinions of the authors and do not commit the organizations or institutions with which they are associated.

## Editors' Introduction

This volume contains the *Papers and Proceedings* of the ninety-seventh annual meetings of the American Economic Association.

The *Proceedings* record the business activities of the Association in 1984; the annual membership meeting; the March and December meetings of the Association's officers and committees.

The *Papers* constitute the greater part of the volume. They comprise seventy-three contributions that fill roughly the same number of pages as two regular issues of the *American Economic Review*. About a year in advance, the Association's President-elect, acting as program chairman, decides on the topics for which sessions will be organized. This is done after consultation and comment, both volunteered and solicited, from a wide range of individuals. (A *Call for Papers* is published annually in the Notes section of the December issue of the *AER*.) The President-elect invites persons to organize these sessions. Each session organizer in turn invites several persons (usually two or three) to give papers on the theme of the session, and asks others to give comments on the papers. The program chairman decides at the time of organization which sessions are to be included in this volume. Space limitations restrict the number of printed sessions. This year we are printing 26 sessions, although a total of 107 sessions were sponsored, either solely by the American Economic Association or jointly with other allied societies. There has been no standard practice with regard to the publication of comments and discussions in the past. This year the President-elect chose to publish no comments, given the difficulty and the invidious task of choosing. He has arranged instead that the names and addresses of commentators be printed at the start of each session, permit-

ting readers especially interested in particular comments writing to the commentator for a copy of the discussion.

The guidelines under which papers are published in the *Papers and Proceedings* differ from those governing regular issues of the *Review*. First, the length of papers is strictly controlled. Except in unusual circumstances they must be no more than twelve typescript pages in three-paper sessions, and eighteen typescript pages in two-paper sessions. Second, papers are not subjected to any refereeing process. Third, their content and range of subject matter reflect the wishes of the President-elect to investigate and expose the current state of economic research and thinking. In most cases they are therefore exploratory and discursive, rather than formal presentations of original research.

While authors are encouraged to submit their manuscripts earlier, in practice most are submitted at the meeting itself, or in the four days following. Very rigid deadlines must be met and there is no time for communication with every author about editing changes made in order to improve content and style, and to satisfy space restrictions.

Every effort is made to notify an author prior to the deadline if paper is too long, or does not satisfy other restrictions on footnotes, tables, and figures. However, sometimes a manuscript is not submitted or revised on time and cannot be published. We are sorry to have to report that this occurred in one case this year. A paper is also rejected if, after reading it, we conclude that it is utterly without merit. This year we are pleased to report that no paper has been rejected on this ground.

JOHN G. RILEY  
WILMA ST. JOHN

## RICHARD T. ELY LECTURE

### Economics in Theory and Practice

By SIR ALEC CAIRNCROSS\*

Do you not know, my son, with how  
little wisdom the world is governed?

*Oxenstierna*

Let's face it. Whatever economics was in the past, it is now virtually an industry. It stretches from the building of new models by the theorists to the supply of advice, forecasts, proposals, and programs by the practitioners, and caters mainly for a market of policymakers in business and government. In the economics business, market forces work feebly, particularly at the level of theory. The competitive process derives little benefit from price adjustments, and suppliers are often remote from the market and unaware of market pressures. But the usual phenomena of growth and development are all at work: investment, economies of scale, and the interaction between technical innovation and market expansion. Some of our colleagues confine their activities to production while others occupy themselves with the business of packaging and marketing. Division of labor has made rapid progress, both horizontally and vertically. On the one hand, we have specialists in different branches of economics: macroeconomics, industrial economics, transport economics, health economics, international economics, mathematical economics, etc., etc. On the other hand, we have a lengthening chain of intermediaries between the priestly who live in clouds of theory and the lay brethren in Washington, Whitehall, and elsewhere, who do battle in the corridors of power. Where so many labor, their efforts merit scrutiny as yet another branch of economics.

I do not propose today to embark on so ambitious a task as an exposition of the economics of economics. Having spent half my working life in a succession of government departments and international bodies, I thought it best to set myself a more modest task and draw on my own experience as an intermediary in the market for economic advice. I propose to limit myself to an examination of the links between theory and practice, between the theorists who seek to trap the inner secrets of the economy in their models and the practitioners who live in a world of action where time is precious, understanding is limited, nothing is certain, and noneconomic considerations are always important and often decisive.

Action can take two forms. It may go no further than policy recommendations, or it may consist in taking policy decisions. When I speak of practitioners I shall normally have in mind those who busy themselves with what the policy should be, whether professional economists or not, rather than those who take the final decisions on policy. But I may on occasion feel obliged to refer to the difficulties of the decision taker in making use of economic advice as opposed to those of his economic advisers in formulating it.

When one looks around, theory and practice are often far apart. In many countries there is even a physical separation: the theorists remain in their universities, the practitioners in their departments of government, with little contact between the two. And since ideas circulate most freely through personal contact, the physical segregation carries with it an intellectual segregation. The thinking of advisers on policy proceeds largely in isolation from the thinking of the academics. Even in countries where there is some circulation between universities and government, and some mixing of one set of

\*St. Peters College, University of Oxford, Oxford, England.

economists with the other, there is a strong tendency for the thinking of each to stay within its own orbit, the insiders pursuing lines of thought independently of contributions from outside, and vice versa.

It is hardly surprising that there should be some divorce between theory and practice when their starting points are so different. As in medicine, engineering and other human activities, one can ask either: "what is the truth of the matter?" or: "what ought I to do?" according as one's interest is in theory or practice. An economist entering a business concern or a government department, unless consigned to the outer darkness of a research section, finds himself in an atmosphere where action takes precedence over intellectual speculation. The question at issue for the practitioner is always: "what is to be done?" That is a question which the pure theorist may decline to answer because he feels that he has no special competence to do so. He may share the view of Nassau Senior that "the conclusions of the economist, whatever their generality and truth, do not authorise him in adding a single syllable of advice."<sup>1</sup> But it is not a question that can be evaded; and presumably a training in economics is of some help in answering it.

How much help does theory provide? Sometimes the honest answer is "very little." It may elucidate, but certainly does not resolve, controversial issues of economic policy. An obvious example is the controversy in Britain in the early 1970's over the desirability of joining the Common Market, with half the academic economists signing a letter in favor, and the other half signing a letter against. Or one can point to the conflict of view between those who put their faith in monetary policy and those who regard it as a broken reed, or between the advocates and opponents of floating rates of exchange, or between those in favor of and those against a statutory incomes policy. Even when the theorists are in agreement, the issue of policy remains undecided. There is widespread agreement that in theory an expenditure tax is preferable to an income tax. But so far as I

am aware, the Finance Ministries of the world have remained unmoved. There has been no rush to change over to an expenditure tax and the only countries which did, India and Sri Lanka, gave up the experiment almost at once.

The limitations of economic theory were brought home to me when I was asked to organize a course of instruction for senior administrators who had come to Washington for six months to learn as much as possible about the kind of economic policies their countries ought to pursue. They did not want to study economic theory as such, and had indeed no time in which to master it, but were interested in the practical upshot of economic thinking and speculation about economic development. They asked quite simple questions—some of them with a familiar ring—such as: "can inflation assist or does it retard economic development? How much can one safely borrow abroad? What tax system is most likely to favor economic development?" I found, as you might expect, that economic theory was indispensable for analyzing their problems, but that it very rarely allowed one to arrive at policy conclusions with any confidence.

Later I encountered a similar group who had come to study investment appraisal and had become well versed in the theory of discounted cash flow. But investment appraisal involves a lot more than economic theory. I asked the group what rate of interest they would use on their return home. There was a long pause until one bold spirit suggested "Bank Rate." Nobody contradicted him. Nobody had other suggestions to offer.

An earlier occasion on which I asked myself to what use I would be able to put my knowledge of economic theory was when I joined the British War Cabinet Secretariat in 1940. There could be no doubt of the profound influence on policy in wartime of a comparatively small group of professional economists. And yet I never saw much use made of the more refined and esoteric parts of economic theory. I concluded, as my colleague, the late Ely Devons put it, that "in so far as economic theory is useful in enabling us to understand the real world and in help-

<sup>1</sup> Quoted by John Jewkes (1953, p. 29).

ing us to take decisions on policy, it is the simple, most elementary and, in some ways, the most obvious propositions that matter" (1961, pp. 13–14). But, as he was careful to add, before the simple propositions become part of normal processes of thinking and cease to be "kept in a separate compartment labelled 'economic theory,'" familiarity with the subject needs to advance well beyond the elementary level (pp. 25–26). Lionel Robbins said much the same when he argued that

...the most useful economic principles, when stated in their most general form, seem often mere banalities, almost an anti-climax after the formidable controversies amid which they have emerged. Yet experience seems to show that, without systematic training in the application of such platitudes, the most acute minds are liable to go astray.<sup>2</sup>

I found that two or three rather elementary economic concepts, which I had assumed would be familiar to everyone, were often not at all well understood by non-economists but were of particular value in policy formulation. Among these concepts I should include as of first-rate importance the idea of the interaction of supply, demand, and price; the concept of opportunity cost; and the marginal theory of value. Later, I concluded that it was even more important to be able to think of market forces operating within an economic system, and to recognize the coordinating function of the price mechanism. Many other elementary concepts, particularly at the macro level, were equally fundamental, but these examples are enough for purposes of illustration.

Noneconomists have rarely sorted out in their mind how supply and demand operate on market prices and have no instinctive appreciation of the virtues—indeed the indispensability—of the price mechanism. On the contrary, their bias is almost always to-

wards an organizational or political approach to economic problems. They like fixed prices because they seem to inject an element of stability and predictability. During and after World War II, when something became scarce the immediate reaction of business men or bureaucrats was nearly always in favor of control and rationing without any thought for the contribution that *some* rise in price might make to relieving or ending the shortage. The pricing of coal, for example, at the time of the nationalization of the industry in Britain in 1947, paid not the slightest regard to the chronic shortage of fuel and the danger that that shortage would arrest industrial recovery, as in the end it did. The pricing of foreign exchange, in much the same way, was divorced from market pressures and continued to be regarded by ministers as a moral or organizational issue: they believed that planning and control could do all that devaluation of the currency could do.

Of course, economists may fall into the opposite error and think that market forces, left to themselves, will always do the trick. At the end of World War II, when practically every country except the United States was running a balance of payments deficit, there were those who regarded the dollar shortage as an invention of governments that were determined to prolong the shortage by overvaluing their currencies. How far rates might have to fall and what the consequences of such a fall might be were matters rarely explored. In the early postwar years, with demobilization in progress and production well below capacity, it was not at all self-evident that a general realignment of currencies and a consequential revamping of the price structure would do much to restore balance of payments equilibrium, however necessary it might prove later on. On the contrary, there was good reason to take direct action to limit imports, encourage exports, develop alternative sources of supply and restrict the export of capital, that is, to make use of planning rather than prices.

Similarly, at the outbreak of war the necessary reallocation of manpower cannot easily be brought about by market forces alone. It might be possible in theory to work

<sup>2</sup>Quoted from an official wartime memorandum in my *Essays in Economic Management* (1971, p. 203).

through variations in the funds at the disposal of different departments and agencies, but if the government means to impose its priorities on the market it will achieve quicker and more predictable results by direct methods. Where a major upheaval is required, market forces operate slowly and blindly.

Opportunity cost is another concept that does not come naturally to the noneconomist. Few people have given thought to the inner meaning of "cost," or habitually decide on a course of action on the basis of the alternatives that might be adopted. Yet in my experience the concept is indispensable in policy analysis and lends itself to very wide applications. This is equally true of the idea of the margin: the average man thinks of averages rather than increments and often goes off on the wrong tack for this reason, particularly in relation to pricing and investment decisions.

Both concepts, however, need careful handling. Marginal theory is usually taught in terms of a single margin when in fact there are a great many. No businessman thinks of output and prices as his only variables, and even when he does, has to consider the repercussions of changing either of them over a whole series of time horizons. With opportunity cost there is a similar danger of neglecting the full range of possibilities. Lord Kaldor has recently used the concept to justify keeping open high-cost coal mines under conditions of heavy unemployment. But the logical conclusion of his line of argument is that so long as there is substantial unemployment, no firm should ever be allowed to close down and no one should ever be sacked, since it is better to have some output than none. The alternatives compared have to have regard to the full consequences, not just the immediate ones.

When I read the literature on shadow prices I have a rather similar reaction that the idea of opportunity cost can be carried too far. The notional prices corresponding to the opportunity cost of capital, labor, or foreign exchange may be enforceable on the limited sector of the economy under the government's control; but that introduces distortions between the controlled and uncontrolled sectors, which may thwart the

government's intentions. Besides, the enforcement of shadow prices that diverge widely from market prices is far from easy, even within the controlled sector. Subordinate authorities are apt to take little notice of a hypothetical test rate of discount in deciding on their investment program and do their sums on the basis of the rate they have to pay on borrowed money, diluted by any subsidies from the central government. To make a shadow rate take effect throughout the public sector, the central government is unlikely to get very far by directives unsupported by offers of capital at the shadow rate.

The biggest single advantage that economists have is their way of thinking. It comes naturally to them to think in terms of alternatives and to trace the implications of alternative lines of action within the logical framework of an economic system. They are alive to the interaction of economic forces within that system and hence to the full economic impact of policy decisions. They are not at a loss, like Prime Minister Attlee, to understand how it is that when activity is so brisk at home there should be so much trouble with the balance of payments. They do not need to be persuaded like Lord Radcliffe—perhaps the most outstanding lawyer of his day—that an enquiry into the working of the monetary system may involve a study of the working of the capital market (though I must admit that there are professional economists who even now seem to share Lord Radcliffe's view).

The importance of an adequate framework of thought was strikingly illustrated in the controversy over central economic planning after World War II. Administrators and politicians alike tended to overlook the role of the price mechanism in their enthusiasm for planning. Two of the most outstanding figures of the period, Sir Oliver Franks and Sir Stafford Cripps—one a top administrator and later Ambassador in Washington, the other a memorable Labour Chancellor of the Exchequer—published expositions of the case for central planning without any hint that there are always powerful forces at work to close any gap between supplies and requirements and that it may be well to pay

regard to these forces.<sup>3</sup> Few administrators or politicians, unless trained in economics, perceive that there can be no question of relying exclusively on government planning, or alternatively on the price mechanism, and that the real problem is always how to combine the two.

It can happen, as in wartime, that the price mechanism plays only a minor part because the government's priorities must take precedence over those of individual consumers; and in the wake of such circumstances the role of prices may be overlooked. It can also happen that economists are so mesmerized by the price mechanism that they limit their vision to the study of market forces when the phenomena of government planning merit equal attention. Just as administrators may fail to understand the workings of the price mechanism, so economists are apt to disregard organizational influences on economic activity. What goes on *inside* the firm, *inside* the government department, *inside* the Cabinet, is often left on one side. Yet it cannot make sense to pursue the study of market failure and undertake no systematic analysis of the weaknesses of alternative agencies of coordination.

To the four elementary economic concepts I have just discussed—supply and demand, opportunity costs, the margin and the economic system—I could add some familiar maxims such as “Bygones are forever bygones,” or “There is no such thing as a free lunch.” These, too, are very helpful in coping with muddled thinking in high places. They form a small but indispensable part of the economists’ stock-in-trade. Where the full range of tools is most likely to be brought into play is in economic forecasting. Here indeed the practitioner has to keep in close touch with current theory. The relationship between theory and practice in economic forecasting raises many interesting questions, since those who prepare the forecasts and are

perhaps best equipped to judge the risk of error may have little contact with those who use them and run their risks on the basis of the forecasts. But economic forecasting is much too large a subject for me to do more than touch on.

I turn instead to examine some of the reasons why economists find difficulty in bringing their theoretical apparatus to bear on practical problems. As Jacob Viner, who had plenty of experience, emphasized years ago, “the list of handicaps of the economic theorist as a participant in public policy...is discouragingly long” (1958, p. 109). Some of these handicaps arise from the practical difficulties that attend the use of economic theory in trying to work out an appropriate policy; others relate to the presentation of the policy so that it carries conviction and obtains support; others again derive from the need to marry economic with noneconomic considerations in making a policy acceptable. Let me take these in turn.

#### I. Limitations of Economic Theory

Economic theory is fundamentally an exploration of models and conceptual relationships couched in hypothetical terms and necessarily abstracts from many features of the real world. Without abstraction and simplification it would not be possible to begin thinking about economic problems. There is no option but to leave out what may seem to some people highly important. As Wicksell pointed out, it is not to be expected that economic theory should attach significance to the features of the real world according to their prominence in the eyes of the layman since “it is not the purpose of science to describe the obvious in elaborate terms” (1934, p. 19). But abstraction can be carried too far. The theorist may follow paths that lead him further and further from the real world and expose him to the danger of what one economist has called “theoretic blight” (E. R. Walker, 1943, p. 57). He may be tempted to select problems that lend themselves to sophisticated technical analysis rather than on grounds of practical importance; and become lost in admiration of the conceptual schemes he has developed without

<sup>3</sup>Sir Oliver Franks (1947); Sir Stafford Cripps’ exposition appeared anonymously in the *Economic Survey for 1947* (Cmd 7046).

regard to the unrealistic premises on which they are constructed. He may also make the common mistake of getting things the wrong way round; or leave out what really does matter or can only be left out provisionally. He may then be deceived into thinking that he understands how things work when in fact the model is misconceived. Theory, as someone once put it, can be "an organized way of going wrong with confidence." To be a useful guide it has to separate correctly what is adventitious from what is truly significant.

Economic policy, on the other hand, has to deal with practical problems and specific situations. While it is possible to develop a branch of economics bearing on these problems and situations and call it applied economics, such a branch is still part of economic theory. It still consists of a set of logically consistent propositions and abstracts from many of the circumstances that may in practice govern the policy pursued. What is to be done is never a simple corollary of theoretical conclusions.

The need for care in drawing conclusions from theory was brought home to me in Berlin in the winter of 1945-46 when I took part in a discussion between Sir Paul Chambers (later Chairman of I.C.I.) and General William H. Draper (then Economic Adviser to General Clay). Sir Paul, challenged as to the accuracy with which he had been able to forecast budgetary revenue as Director of Statistics and Intelligence in the Inland Revenue, gave us a short exposition of the theory of probability. "If you toss a penny and it comes down tails ten times in succession," he said, "that doesn't affect the probability that it will come down heads next time. The chances remain fifty-fifty." "Shall we test that?" said General Draper, producing a penny. "Will you call?" Ten times Sir Paul called heads and each time the penny came down tails. Before tossing it again, General Draper revealed that the exercise of a little sleight of hand might be affecting the behavior of the penny. It is always necessary to enquire whether the assumptions of theory are valid in the case at hand before applying it; and if the facts do not conform to theoret-

ical expectations it may be the facts that need looking into, not the theory.

Whatever the limitations of economic theory, it is very powerful stuff, more powerful the more general it comes. We certainly cannot dispense with it in trying to understand any economic system. If we enter a maze we need a thread to guide us in it and the purpose of theory is to furnish that guide. On the other hand, we cannot hope to get very far with theory alone and there are serious dangers in moving from the world of theory to the real world without regard to the difference between the two. One danger is that the theory may be obsolete. It isn't just the practical man who may become the slave of some defunct economist. Even professional economists, deeply immersed in their everyday duties in some government department, have to live on an intellectual capital that is rapidly depreciating and need an opportunity of rebuilding it in an academic environment. There may also be times when the boot is on the other foot and it is the practitioner who is alive to truths disregarded in current theory. Theory may suffer from a distortion of emphasis or a quirk of intellectual fashion that throws into prominence the wrong variables, the wrong problems or the wrong formulations of them; attention may then be diverted from the things with which theory should be occupying itself. When that happens, economic theory must be accounted not just irrelevant, but bad: for the primary purpose of theory is to assist us in posing questions, and if we are moved to ask the wrong questions theory has failed us.

The most serious problem for the practitioner is that the theorists differ, even on technical economic issues. There is no agreement on how the economy works—on what governs the level of output or employment or prices. Where the disagreements go so deep as they do nowadays it is difficult to speak with authority on technical economic issues. I need not dwell on the problems this creates in advising on policy.

And yet there are times when I wonder whether the disagreements between economic theorists, even now, go so deep as

their solidarity when confronted with the heresies which so often shape the policies of governments. To take an extreme case, we may debate whether the money supply is too great or too small: but what of governments—and there have been some—that try to do away with money altogether or come to power, like the Social Credit party, preaching that there is never enough? Or, to come nearer home, what of the comment made to me on the Radcliffe Committee by the President of the National Union of Mineworkers, one of Arthur Scargill's predecessors: "You fellows seem to worry about what the rate of interest should do. But my members don't see why there should be a rate of interest at all." Or, still on the subject of interest rates, what are we to make of Chancellors of the Exchequer who exclaim like Hugh Dalton: "You can't allow higher interest rates while resisting higher wage rates." It can sometimes be easier to reach agreement between economists on what should be done than on matters of theory.

A further difficulty facing the practitioner relates not to theory but to economic information. Economic theory has always to be mixed with a large dollop of fact before prescriptions for action can be framed; but the facts are usually obscure, disputed, seen through different eyes against a different experience of life and stretching far beyond the limited economic context within which the economist seeks to analyze them.

The theorist moreover is in control of his starting point, since he is free to make his own assumptions; but the practitioner is never quite sure where he is. As Lord Roberthall, who was Economic Adviser to the British government for fourteen years, used to say: "it's very hard to forecast where you are now." Indeed, you don't even know where you *were*. The official statisticians are busy rewriting history from the word "go"; and they don't stop. When I look back at the British balance of payments deficits in the three years after World War II, for example, I find that the figures for the current account first published added up to £1245 m., were revised by 1953 to show a total of £740 m., and continued to be revised over the next

thirty years until they dwindled to £585 m. Instead of working out at exactly the level assumed in the Washington Loan Negotiations in 1945, the cumulative deficit is now put at less than half and British capital exports over the period are consequently estimated at a total higher than was thought at the time by \$2½ b., that is, by two-thirds of what was borrowed from the United States. Another example is the way in which the U.K. monthly index of industrial production in 1964 was completely flat in the nine months up to September—a General Election was due in October—but was revised over the next two years so that it was sloping steeply upwards in official publications in 1966 and then was further revised until now it is flat again, as in 1964.

I cite these changes, which could easily be multiplied, to show that if the future is uncertain, so also is the past. I have often been intrigued to see how patiently economists apply themselves to explaining what, if later information is to be trusted, never occurred and how figures of assorted reliability are given equal treatment by those who do not live among them. The practitioner, recognizing the uncertainty of the information at his disposal, can have only a limited grasp of what is going on. He has to make the best of incomplete, inconsistent, and changeable data, relying on human judgment to derive a plausible, self-consistent picture of the existing situation. He is quite likely to find, as I have found, that the best way to reconcile the data is to begin by making a forecast of the future as a way of deciding on the underlying trends and then work backwards to a consequential interpretation of the present. The judgment he makes—as in the examples I have cited—may be crucial to the choice of policy. If for instance, you think the economy is stuck, you opt for policies very different from those appropriate to a rip-roaring expansion.

A further difficulty is that the economy never works in quite the same way for very long. You may feel confident that you can explain how it worked in the recent past and set your conclusions down in equations with all the coefficients, lags, etc., carefully esti-

mated. But, as Keynes put it, human behavior is not "homogeneous through time."<sup>4</sup> Whether you realize it or not, you are always working with relationships that are obsolescent without knowing just how obsolescent they are. One day you can count on people spending more when prices go up; then you find them spending less. One day the unemployment figures go up when the vacancy figures come down; then they both go up together. It is always necessary to be on the look out for some departure from normal patterns and pay attention to straws in the wind. They may reveal, earlier than any statistics, new forces at work or a strengthening of existing forces. Analysis of these forces has to be coupled with a good eye for straws.

Then there is the limitation imposed by the need to be specific: in particular, to deal in specific magnitudes and at specific points in time. Many of the more important generalizations in economics make no reference to magnitudes or time. They may be of assistance to a government that wants to know in which direction it should be operating; but they do not, in their general form, offer much help to a government wanting to know how far to go.

For example, it may be possible on general grounds to indicate that the government should be thinking in terms of increasing taxation. But the question that has operational significance is, how much should the increase be? This requires immersion in a mass of statistical detail and the working out of far more definite views of the functioning of the economy than found their way into the traditional textbooks in economics some years ago.

Then there is the content of the tax package. What *taxes* should be increased? What effect will the increases have? What other action, if any, should accompany the increases in tax or be contemplated for introduction later?

Another set of issues relates to timing. When should the government act? When will

it be possible to judge whether the action has been effective? Is it likely to be necessary to take further action later?

It takes time to become aware of changes in the situation, to size up the strength of the forces at work, to prepare the appropriate response. One cannot wait for certainty, but it is also a mistake to act prematurely when the diagnosis may prove to be quite wrong. Delay may be inescapable. After the devaluation of sterling in November 1967, there was a great burst of consumer spending and a clamor for early action to restrain it. The right time to act was of course in November, but when that opportunity was missed it was not easy, for technical reasons, to redeem the error by imposing additional taxation in the weeks immediately before Christmas. In January it seemed better to put all possible effort into a battle for lower government expenditure and by the end of the month the budget was already in sight only a few weeks away. So although the need for action was not in dispute, it was four months before a suitable package of measures could be introduced.

Another source of difficulty is that many of the questions on which advice is sought from economists have very little to do with conventional economics. Cabinet ministers, I found, don't ask the questions you are ready to answer. They want to know how people will react, both to events and to their policies. Will there be a strike or won't there? Will the rate of exchange weaken or strengthen? Will it be possible to get backing for this or that line of policy?

I concluded that attitudes were just as important as prices and that economic policy had to embrace efforts to change attitudes, not just efforts to make better use of market forces. Just as economic events and policies may have their biggest impact outside the functioning of the economy—as world depression could clear the way for Hitler—so of the most effective levers of economic policy sometimes bypass the market operate on confidence and opinion, expectations and attitudes. In the same way as economists so often neglect goodwill in discussions of industrial economics, so they tend to neglect the prestige, credit, standing,

<sup>4</sup> Keynes to Harrod, *Collected Writings* (1973, pp. 296–97), quoted by Bernard Corry (1978, pp. 5–6).

authority—call it what you will—of governments and the ways in which morale and endeavor are affected by factors other than pay.

## II. Presentational Difficulties

Let me turn next to presentation. This raises problems at two levels, that of the theorist and that of the practitioner.

Theorists may confine themselves to the business of producing theories without much regard to the market for them. But in applying economics in practice, it is impossible to overlook the importance of the consumer. This is obviously true in the short-run sense that one has to have regard to the chances that any attention will be paid to suggested lines of action by those who have it in their power to act on them. It is true also, in a much wider sense: that those parts of economic theory that do not supply useful answers tend to receive little attention in business or government, while those that purport to throw light on practical problems, and point in the direction of specific ways of dealing with them, command respect and interest.

Practitioners face a rather different problem of presentation. Governments are almost as much concerned about what to say and how to say it as about what to do. Indeed, what they say may have more effect on the markets than what they do. They may be given credit for cutting public expenditure by simply announcing that that is their intention even when, as in the first four years of Mrs. Thatcher, it continues to increase. Similarly they may be given credit for mastering inflation when all they have done is to contribute to an international depression that brings down import prices. The public reacts to the declared aims of government as presented in speeches, often without close enquiry into the success with which these aims are pursued. This being so, economists can neither ignore how policies are presented nor how market opinion may narrow the scope for government action. Against the extra leverage that skillful presentation of policy may provide must be set the danger that the government may become the prisoner of

market opinion, forced to conform to the role assigned to it by that opinion, and so transmuting into rational expectations what would otherwise have no rational foundation.

The issue of presentation is obviously highly important when any major change of policy takes place. If, for example, a more restrictive policy is proposed involving higher taxes, the Minister of Finance needs to see the case presented in persuasive terms so that the government, in turn, can be persuaded and the new policy defended in public debate. There is always a question how the higher taxes can be presented with the minimum damage to the credit and authority of the government and its capacity to carry through the rest of its program. What is to be said and how is it to be said? The handling and presentation of the decision is part of the decision itself and cannot be dismissed as irrelevant to it. It is partly because this is so that it becomes difficult to find a use for those parts of economic theory that are not easily translated into simple language.

Taxation provides many illustrations of the problem of presentation. I can remember Chief Festus of Nigeria recounting how he had to withdraw a tax on cosmetics because, as he explained, holding up a large, pudgy hand, "I burnt my fingers." In Britain the Selective Employment Tax introduced in 1965 was withdrawn six years later, in part at least because the refined economic logic by which it was justified did not make sense to the general public. Or take corporation tax. Economists might agree that there is no strong case in theory to have a corporation tax at all. But a proposal to abolish the tax would certainly be laughed out of court by politicians and would be unintelligible to the general public.

In stressing presentation and acceptability, I should not want to be interpreted as defending mere sycophancy and time-serving, automatic approval of any act of policy that is likely to gain popular approval and command a Parliamentary majority. Neither Parliament nor the public has any prerogative of wisdom in economic affairs, whatever democratic theory may imply, and the test of sound policy can never be made on accepta-

bility alone. On the contrary, the economist is wise to be on his guard, as Marshall emphasized, when his views are popular and all men speak well of him (cited by Pigou, 1925, p. 89). He owes it to his profession to speak up for what he thinks right, to denounce policies that he thinks mistaken and to try to persuade those in power of the dangers they run if his advice is neglected. But if he wishes to be heard, he has to learn when to keep his peace and when to press his point. There are times when policies have to be ruled out because the political leadership required for their adoption simply does not exist; and when indeed the policies that seem right to the economist in his study might provoke adverse reactions, of which he has taken little or no account, but would make nonsense of the policies. There are other times when new ideas could fill a political vacuum, and what was previously unacceptable can be taken down from the shelf and put on sale.

In practice, political choices are rarely a matter of good and bad, black and white. They usually turn on a balance of considerations among which economic factors are not decisive. I don't know what undergraduates make of the questions they are asked to decide in three-quarters of an hour in final examinations. But if they have difficulty in coming to firm conclusions they are in good company. One can make a case—and generally quite a respectable case—for a variety of economic policies at any point in time and argument is unlikely to destroy every case but one and leave the surviving case as indisputably "right." Economists do notoriously disagree. So what they have to square with their conscience is usually not failure to demonstrate the error of some politician's ways but failure to offer the right degree of resistance, to do battle with the right degree of conviction, to use what Lord Roberthall once designated "the right tone of voice." Like the lawyer, the economist comes to see the case that can be made for and against, and loses the campaigning spirit with which he set out. He has to be forever pointing out that things are not quite so simple as politicians suppose, forever dwelling on the hidden snags. Policies cease to be right or wrong,

but just better or worse, and often only marginally so. The occupational disease that he has to fight is not time serving but atrophy of conviction and the sense of commitment.

### III. Noneconomic Factors in Economic Policy

I come next to the implications of the obvious fact that the policies of governments are by definition a political matter. If you are considering what governments should do, you can hardly avoid taking account of what sort of government you have, and how much government you want. It makes quite a difference whether you have been brought up to regard the government as Santa Claus, Stalin, or a dog fight. One government may be benevolent, another dictatorial, a third incapable of making up its mind. All of them have the failings of their human components, ministerial and bureaucratic.

Governments are political animals, moved by political considerations. They have to ask themselves what they *can* do and this may rule out many otherwise attractive lines of action. There are commitments by which they are bound—to other governments, to particular interests, to the party supporting them in office. They hesitate to fly in the face of prevalent attitudes and opinions. They are more conscious of immediate pressures and short-term considerations than of what is desirable in the long run and usually prefer to put off the evil day. Even when they are anxious to do the "right" thing, as a surprising number are, or when they give priority to long-term objectives over short, they tend to do so with an obstinacy fatal to their hopes: either because they lack understanding of the appropriate sticking-points, or because they hesitate to give ground for fear of unsettling opinion and losing the support they need. One of the most difficult problems in policymaking is to know how far to persist and when to bend. Overcommitment can be worse than opportunism.

In any event, the economist has to recognize that policy does not take shape in a vacuum but within a machine that has several well-defined organizational characteristics with which he would do well to become acquainted. Government is not a simple opti-

mizing activity that can be reduced to a second differential in a mathematical equation. It is more likely to be a collection of bald-headed and somewhat bewildered men sitting round a table, harassed and short of time, full of doubts and dogmatism, with all the strengths and failings of successful politicians. Such men may survive for a long time without any policy at all except in the form of a series of specific responses to matters forced on their attention and calling for immediate decision.

If, therefore, the economist wants to influence policy and asks where policy is formed, the answer may be either anywhere or nowhere. It is not unknown for political theorists studying a government department to come to the conclusion that no intelligible answer can be given to the question: "who forms policy?" A succession of battles on a succession of issues may rage within or between departments, involving different groups at different times, and there may be no consistency in the outcome of their debates except what is imposed in ignorance by some later historian. Or decisions may be taken low down in the hierarchy by someone who is unaware that he has taken any decision at all (such as the decision to do nothing); and although the matter may be fought out at increasingly exalted levels until it reaches the Cabinet, ministers may have no option but to accept the inevitable, even if so little disposed to recognize their own impotence that they go through the charade of further debate and carefully minuted decision. It is one of the curiosities of government how frequently what is plainly due to the force of events is attributed to free and deliberate choice.

This is not to say that policy itself is a hallucination and not worth bothering about. What governments do can hardly be discussed in such a ludicrous fashion. The point is rather that one has to understand the scope for policy, the times at which it may be influenced, and the pressures that govern it. Similarly, one has to have some awareness of the bureaucratic atmosphere within which economic problems arise and have to be tackled. That atmosphere is somewhat different from the comparative calm of university

life. Many years ago I described how "the various divisions in many government departments (were) loosely geared together, uncertain of the limits of their responsibilities, losing and gaining staff almost every week, themselves dissolving from time to time into new divisions or subdivisions, and facing an avalanche of fresh problems on which to advise, fresh cases to decide, and fresh policies to apply."

No doubt that exaggerates a little; but it brings out some of the features of life with Leviathan that an academic economist might overlook. These features condition the way in which economic theory impinges on policy and limit in particular the chances of drawing on highly complex bits of theory.

Allowance has to be made next for the political setting: the need, if one is in business, to guess what the government will do next, or, if one is in a government department, what is likely to prove feasible and acceptable to a government wishing to stay in office. A wise decision on what should be done cannot be based on economic reasoning or models that pay no regard to the distribution of political power, the frame of mind of the public, or the political ambitions and anxieties of the party in office.

Suppose, for example, that one thinks, like one of my distinguished Cambridge colleagues, that the economic situation calls for the use of import restrictions. One may begin by setting out the economic arguments. Then one has to reflect on the political situation. If on January 1, 1973, Britain has just joined the European Economic Community, one has to ask whether it makes sense to urge ministers *a week later* to introduce import restrictions that will fall heavily on imports from Common Market countries. If in June 1975 a referendum is to be held on continued membership of the Community and the Cabinet is split down the middle on the issue, one has again to ask if it makes sense to press the Chancellor, just ahead of the referendum, to budget in April for import restrictions, especially if the identical remedy was appropriate two years earlier in very different circumstances. If the advice is accepted and an international row brings on a run on the pound, how is the Chancellor to explain to

the IMF that he acted in the interests of greater stability in the exchange rate, and how is he to put it to his continental colleagues—most of them struggling with heavier unemployment than Britain—that he felt compelled by the intolerable level of unemployment to set aside his treaty obligations.

It is not only the organizational and political setting that is important. Economic problems have also to be seen in their institutional setting. It is (or should be) impossible to discuss monetary policy without regard to the kind of banking system and methods of credit control in operation, just as it is or should be impossible to discuss wage theory without regard to the way in which wage bargains are struck and bringing in various kinds of legislation affecting bargaining power (for example, in relation to minimum wages, the powers and practices of trade unions and employers' associations, redundancy, labor mobility, and so on).

Frank Knight in his latter days used to agonize over the futility of being an economist. He doubted whether society would ever take advantage of anything he had to contribute to the solution of its problems. Others like Max Planck have turned away from economics because of its appalling complexity. Others again have given up in despair of arriving at finality: they are repelled by the inconclusiveness of the subject—what Wicksell called “the permanent state of war” (1958, p. 52) between diametrically opposed views neither of which is ever vanquished or disappears from the field as would happen with the natural sciences. There is no received body of doctrine—only a “technique of thinking.”

In spite of what I have said about the limitations of economic theory as a guide to policy, the contribution it can make seems to me none the less invaluable. Any doubts on that score are soon quelled by life among noneconomists in positions of power. Moreover, the very inconclusiveness of economics has its value as a preparation for the world of affairs where the same inconclusiveness rules. In government and business there is rarely a conclusive answer; instead there is an equally enduring “state of war.” The evi-

dence on which an answer might be reached, even on matters of fact, tends also to be inconclusive since there is rarely any finality in the statistical data that purport to summarize the facts. It is necessary to decide between alternatives in the light of uncertain and often contradictory evidence. The decision, it is true, rarely turns exclusively on economic considerations. But it is a great advantage to be able to assess the force of these considerations, just as it is also a great advantage to be able to test the data with the kind of insight into the underlying relationships at work that economic theory engenders.

In the application of economics to practical problems, that kind of insight needs to be reinforced by imagination and accurate observation. Imagination is kindled by good theory but is powerless or mischievous if fed with inadequate or inaccurate information. In the social sciences there is no substitute for getting the facts right, and observation ranks at least as high as logic. Most theoreticians tend to treat far too lightly the difficulty of obtaining and presenting the information necessary to a sound decision. If you want to understand how the economy works, you need to have an eye for the information that matters; and since the unexpected keeps happening you need very up-to-date information. An economist like Keynes may owe his reputation to his originality as a theorist; but in my judgment he stands out from the other economists of his time at least as much for his flair in picking on significant statistics, often from relatively obscure sources before anybody else, and piecing them together by conjectural arithmetic to reveal a danger not then fully appreciated. Other economists of the first rank commonly have a similar power to startle with unfamiliar figures that give a new perspective to events.

Those who have done their homework thoroughly, and have mastered every scrap of information likely to be of assistance will be of little use, however, without the imagination to conceive of alternative policies and visualize the reasons why they may not work as expected. They may fail to make use of available information because they do not appreciate its relevance and overlook or mis-

construe important relationships. For example, price control is obviously not enough by itself to remove the danger of inflation in wartime. But it required considerable imagination in World War II to invent three new devices for that purpose: postwar credits (an acceptable form of forced saving); points rationing (the circulation of a new currency to be used exclusively for the purchase of rationed goods); and subsidies to stabilize the prices of key commodities, making up a kind of iron ration. All these were expedients, not intended to last indefinitely, but they did contribute to a general stabilization of incomes and prices.

#### IV. Conclusions

It has been part of my theme that economics has more to offer by way of analysis than prescription. So it is hardly surprising that I should have few proposals for improving the state of affairs I have described. I have three rather modest suggestions.

The first can be put in a word: circulate. The practitioners need to mix with the theorists and vice versa. More than that—the practitioners need to be given a chance to catch up with theoretical developments by release from time to time from their duties. They should be offered sabbatical leave, or enabled to attend conferences or at the very least given time to read the journals. They also need encouragement and opportunities to make their own contributions to current theoretical controversy. Conversely, the academics need a modicum of experience of policy formulation. A spell in government or business can do wonders in changing the outlook of a theorist on the best way of spending his time, on the choice of problems to study, and on the limits within which action can be taken. In some countries, however, including my own, it has become more difficult to move in and out of government. Twenty years ago a remarkably high proportion of top British economists had had experience of service in government. Today there is very little circulation. That seems to me a step in the wrong direction.

Secondly I think we need to revalue and upgrade the work of intermediaries between

the profession and the public. Financial journalism, for example, is an increasingly demanding skill and has become both more sophisticated and professional and more influential since the war. The press also carries articles by professional economists, and a number of specialized publications reprint (or commission) articles by them that help to illuminate current issues. But the mass media are largely untouched by this trend. It may be that nothing can be done about this. But there does seem to me great scope for those economists who have a gift for conveying the thinking of the profession, with all its doubts and dissensions, to the man in the street.

Finally, don't let us be overwhelmed by our disagreements: we have also plenty to agree about. As I have tried to show, it is often the most elementary propositions in economics, on which we all agree, that matter for practical purposes. Similarly, we should not underrate the value of the habits of mind that are nourished by economic analysis, even if they yield no common program of action. Where we continue to disagree, let us try to understand and narrow our differences, remembering always that we have a duty to our fellow citizens to offer them the best advice we can.

## Post-Entry Competition in the Plain Paper Copier Market

By TIMOTHY F. BRESNAHAN\*

This paper reviews events in the plain paper copier (PPC) market immediately after Xerox's monopoly ended. Xerox's behavior and that of a flood of PPC entrants are viewed through the lens of recent advances in the theory of entry and entry deterrence. The events of the early post-entry period also cast some interesting light on the theory of technological competition.

The modern theory of entry deterrence rests on a simple, if not obvious, proposition. The (socially) worst industry performance is after entry, the more monopolies there will be, since the interests of the entrant and society are opposed once entry has occurred. A series of papers have considered endogenous changes in the conditions of competition-monopolists who make their industry more competitive (conditional on entry) in order to deter potential entrants.<sup>1</sup> There are two distinct steps in the entry-deterrence argument. First, it must be possible for events during the monopoly period to affect post-entry competition. Some intertemporal complication must be present, either in costs or in firm-specific demand, if the state of the industry at the time of entry is to form important "initial conditions" for competition. Second, the monopolist must find it profitable to manipulate the initial conditions by some pre-entry action.

The general theoretical questions of entry and deterrence have been cast in quite spe-

cific terms for the problem of technological competition. One view emphasizes the "Arrow effect" (Kenneth Arrow, 1962; Jennifer Reinganum, 1983; Drew Fudenberg and Jean Tirole). Because any innovation destroys some of the rents to older products and processes, incumbent monopolists have a smaller incentive to innovate than potential entrants. Another view (Richard Schmalensee, 1983; Richard Gilbert and David Newbery, 1982) points out that the incumbent's losses from entrant's innovation create a motive for preemptive R&D, product introduction, or patenting. If incumbents are leaders and entrants followers, the second view will hold independent of technology. Note that the difference is over the profitability of entry deterring strategies. In both views, the presence of valuable assets like patents or secrets provides the necessary intertemporal link.

Events in the PPC market during the time of Xerox's monopoly did have a substantial impact on the nature of competition in the early postentry period. An Arrow effect is evident, as are other equilibrium explanations of Xerox's rapid decline. The alternative explanation that Xerox was "fat" is also considered below.

### I. The Late Monopoly in PPCs

Xerox the monopolist did three things which form the basis for my investigation: it price discriminated, priced far from costs, and patented every imaginable feature of the copier technology. The early entrants (in the early 1970's) and the effects of the FTC consent decree requiring Xerox to license its patents to all comers (in 1975) were substantially affected by the initial conditions at the beginning of the competitive period.

<sup>†</sup>*Discussants:* Richard J. Gilbert, University of California-Berkeley; Paul David, Stanford University; Kenneth Judd, Northwestern University.

<sup>1</sup>See A. Michael Spence (1977); Avinash Dixit (1979): See also papers reviewed by Drew Fudenberg and Jean Tirole (1984).

Xerox used a long list of price discrimination devices.<sup>2</sup> Among other devices, Xerox based rental prices on the number of machines a customer used, whether different models were rented by the same customer, by the number of copies per month, and by the number of copies per original. Implementation of this price discrimination scheme required a "lease-only" policy. This is the first of the initial conditions of the period of competition. Xerox had an extremely large rental fleet of copiers at the time of entry. As a result, the capital loss on existing copiers due to competitive price falls would be born by Xerox, not by old customers.

The second initial condition was the result of the umbrella provided by Xerox's price-cost margin. In the small (low-volume) copier market segment, "coated paper" copiers held on to a substantial market share despite their great inferiority to *PPCs*. In the high-volume copier/duplicator market segment, photography-based methods remained common despite their cost disadvantage relative to electrostatic copying ("xerography"). Substantial product-development and distribution-network quasi rents in those industries would be destroyed if *PPC* prices fell.

When IBM and Litton entered the *PPC* market in 1972, Xerox sued to block entry under literally hundreds of patents. IBM had spent millions to "invent around" Xerox's major patents—with 25 percent of the budget going for patent counsel, not *R&D*. Later entrants depended on antitrust countersuits rather than plans to defend the patent suits, as did Litton. Over the same time period, the FTC brought another antitrust action. Over the objections of existing entrants (especially SCM), the FTC forced Xerox to license its patents to *all* entrants at nominal costs.<sup>3</sup>

<sup>2</sup>This discussion, and much of this paper, is in deep debt to staff work done at the FTC in connection with the Xerox case. Comments by R. Gilbert, F. M. Scherer, and several members of the FTC staff on my larger paper (1985) on which this one is based were very helpful. Factual assertions will not be documented in this paper; citations and more detailed evidence are available in my earlier paper.

<sup>3</sup>Existing entrants proposed an arrangement in which they and Xerox would exchange patents.

This was the third initial condition: potential entrants could be reasonably certain as of 1974 that there would be free access to *PPC* technology.

## II. The Transition to Competition I: Prices and Market Shares

Plain paper copiers are complex, highly technical products. Models vary in speed, ability to collate, needed warmup time, and reliability. Firms vary in the degree of non-hardware service they bundle to their machines.

Table 1 shows rates of change of prices indexes for *PPCs* calculated on the basis of standard lease contracts for those machines which do not change (hardware) features between years. These indexes are biased upward when new machines are introduced: in general we would expect the price fall from an existing machine to be less than proportional to the (implicit) price fall from a new machine. Yet they show an extremely rapid fall in the price index immediately following entry. Xerox's prices lag entrants' in this period. (1977 was a major new-product year for Xerox, so the "Xerox" column would show a large drop if it could be calculated.) After 1978, price indexes for Xerox (not shown) move quite closely with those for other firms.

The simultaneous existence of rental and purchase markets complicates the calculation of market shares. Two obvious definitions are possible: share in "installed base," total machines in use, and in "net new placements," current sales plus new rentals minus returns of old rental machines. Xerox's share on both definitions was 100 percent in early 1972. Its share of new placements fell to 58.5 in 1973, 43.2 in 1974, 14.1 in 1975, and 13.7 in 1976. It's share rebounded to 44.5 in 1977 and has remained since then in the 40–50 percent range. In installed base, Xerox's share declined steadily to 55 percent in 1977 and declined more slowly thereafter to a current range of about 45 percent.

The curious thing about this particular transition is the dip in Xerox's market share in net new placements. Two points are worth noting. The first is that during the transition

TABLE 1—PPC PRICE INDEXES<sup>a</sup>

	Xerox	All Firms
1973	-6.9	-8.4
1974	-12.0	-11.8
1975	-2.5	-5.9
1976	-8.2	-2.7
1977	<sup>b</sup>	-7.1 <sup>c</sup>
1978	-6.1	-6.3

<sup>a</sup>Average percent change in real rental price since previous year.

<sup>b</sup>Not calculable: insufficient comparable contracts.

<sup>c</sup>Does not include Xerox Corporation.

period, Xerox did not function as a leader relative to other firms. One could either use the language of the contemporaneous trade press—Xerox “passive” and “fat”—or note the incentive effects of the Xerox rental fleet left over from the monopoly period. In the transition period, each addition to the installed base lowers price, and it is Xerox that takes the largest capital loss on that price fall, since Xerox is the owner of the bulk of the inframarginal units. (The intuition here is that of Cournot.) Thus Xerox is at a considerable strategic disadvantage. After Xerox's installed base declines to what now appears to be Xerox's steady-state market share, this comparative disadvantage is wiped out.

The second thing to note about the entry period is that the transition took almost five years from initial entry and three years from near certainty that the FTC would allow free entry. The adjustment costs for a *PPC* entrant are nontrivial: a distribution network must be set up, a machine must be designed, and so on. It is hard to imagine, however, that these adjustment costs are particularly large by the standards of manufactures generally. This long adjustment period suggests that the entry deterrence theories may be correct in those industries, unlike *PPCs*, where initial conditions tend to give incumbents a strategic advantage.

Theories of entry deterrence and of the persistence of monopoly have naturally emphasized those intertemporal cost and demand relationships which give strategic advantages to incumbents. These are relationships of *complementarity* over time. If capital is long lived, higher production dur-

ing the monopoly period lowers post-entry costs. If users of the monopoly product invest in knowledge of how to use it, their demand curves for that specific brand will be shifted out post entry. By contrast, substitutability over time leads to incumbents' strategic disadvantage, as in the *PPC* case.<sup>4</sup> Since photocopiers are a durable good, their demand is characterized by intertemporal substitution, to Xerox's disadvantage.

Since a large fraction of modern monopolies are producers' durables, there seems to be a presumption that the most common strategic effect is incumbents' disadvantage. This presumption is too hasty, however. At least in electronics, monopoly products are frequently associated with substantial investment in information goods by downstream firms. For example, mainframe computers require downstream investment in software and in human capital, which can lead to a substantial complementarity over time in single-brand demand. This may well give IBM a strategic advantage, contributing to its continuing dominance.

### III. The Transition to Competition II: Innovation

The transition period saw a great deal of innovative activity from entrants and Xerox. It is possible to say something about the impact of competition on the direction of inventive activity based on this experience, although little information is provided about the rate of activity.

The new-product choices of firms whose rents were destroyed by the increase in *PPC* competition are illuminating. We can divide these firms into three groups: producers of coated paper copiers (*CPCs*), producers of photoduplicators, and Xerox, a full-line *PPC* manufacturer. The producers of *CPCs*, having substantial marketing and distribution expertise in the small-volume copier segment, would seem to be a natural group of

<sup>4</sup>This discussion presumes that the incumbents' products and the entrants' products are in a relationship of “strategic substitutability” post entry. See Jeremy Bulow et al. (1984) and Fudenberg and Tirole for a fuller discussion of the strategic issues.

entrants into the *PPC* business. Most did enter, but not into the small-volume segment: in 1976 a group of these firms (SCM, Dennison, AM, A.B. Dick, and Royal) was offering more than three times as many high-speed as low-speed copiers. There was very substantial entry into the low-volume segment, overwhelmingly by firms not previously in the market (Savin, Ricoh, etc.). With the exception of Kodak, which continued to offer differentiated high-volume copiers with all available technologies, photocopier manufacturers did not enter the *PPC* market. Xerox introduced new products in all segments. As a regularity, firms that had a choice chose to enter product segments where higher rates of inventive activity would destroy others' rents, not their own.<sup>5</sup>

As in the last section, we see that initial conditions matter for competition, and in the way suggested by the theory. It is again the incumbent's strategic disadvantage that shows most clearly in the *PPC* case. The logic of the entry deterrence theories is vindicated, but there is no presumption that the demand and technological conditions leading to the persistence of monopoly are common.

Verifying the generality of the *PPC* experience is no easy task. One might be tempted simply to ask whether monopolies and near-monopolies persist in high-technology areas. But all theories will imply that, in a suitably uncertain world, some monopolies will persist and others will not. No preemption theorist feels the results are weakened by RCA's failure (during the 1950's) to preemptively invent processes for producing integrated circuits, nor can any believer in the Arrow effect rule out the theoretical possibility that IBM simply built a better computer than Burroughs (in the 1960's).

<sup>5</sup>Though the immediate post-entry period saw a very rapid increase in the overall level of *PPC* innovative activity, it is not possible to draw any conclusions about the relationship between competition and innovation. It would be extremely difficult to distinguish the effects of important changes in technological opportunity, such as those resulting from the invention of the micro-processor, from changes in the conditions of competition.

#### IV. What is "Fat?"

The trade press of the transition period made much of the idea that Xerox was "losing" because it was fat, language not particularly attractive to economists. There is hard evidence of this fat, however. In the monopoly period, using very successful price discrimination devices, Xerox had price-average cost margins of around 10 percent. From 1972-76, a period with no important advances in *PPC* manufacturing process, prices of standard contracts fell by 30 percent and Xerox's price-discrimination practices ended. Other firms found it profitable to operate at the new prices. Xerox's accounting average cost must have overstated true marginal cost by at least 20 percent.

The trade press also offers a view of the differences among companies' technological tendencies which may imply a theory of where the money went. In the monopoly period, Xerox was a highly innovative firm. But the innovations were characterized by being "in the copier." These were purely technical advances in the quality of reproduction, as well as such features as two-sided copying, reduction, etc. The innovations by entrants include some of a very different character, those oriented toward the "user interface." Entrants introduced document feed devices (Kodak 150), automated many of technical features like two-sided copying (IBM III), and invented whole new product markets like the "convenience copier" (Savin 750.) One of the natural claimants for the rents in a high-technology activity is the engineering staff, not capital. Since capital in fact owns the rents, this requires an explanation of a failure of monitoring. Though taking the rents in the form of cash may be easily monitored, taking the rents in the form of a persistent bias away from the highly commercial activity toward activity of more purely engineering interest may be much more difficult to monitor.<sup>6</sup>

<sup>6</sup>This theory is complementary to Michael Salinger's (1984) observation that union labor may claim the rents.

### V. Conclusion

This attempt at an industry case study may well appear clumsy to experienced practitioners of the art. I note only my surprise at how helpful recent advances in economic theory can be in understanding real competition.

# **R&D Appropriability, Opportunity, and Market Structure: New Evidence on Some Schumpeterian Hypotheses**

By RICHARD C. LEVIN, WESLEY M. COHEN, AND DAVID C. MOWERY\*

One of the largest bodies of literature in the field of industrial organization is devoted to the interpretation and testing of several hypotheses advanced by Joseph Schumpeter (1950) concerning innovation and industrial market structure. One set of hypotheses focuses on the role of firm size as a determinant of *R&D* spending and the rate of technological advance. Another set focuses on the effect of market concentration on *R&D* and technological advance. In this paper, we reexamine the latter set of hypotheses at the industry level, using new data on *R&D* appropriability and technological opportunity collected by Levin et al. (1984) in a survey of *R&D* executives in 130 industries.

## **I. Motivation**

Despite the voluminous literature, theory yields ambiguous predictions about the effects of product market concentration on *R&D* spending and on innovative performance. For example, it is often argued that firms in concentrated markets can more easily appropriate the returns from their *R&D* investments. On the other hand, it is argued that gains from innovation at the margin are larger for competitive firms than for monopolists, but this argument neglects systematic differences in the probability of imitation or in costs of adjustment. Schumpeter himself emphasized that concentration reduces market uncertainty and provides the

cash flow required to engage in costly and risky *R&D* on an efficient scale. Others have argued that insulation from competitive pressures breeds bureaucratic inertia and discourages innovation. Still others have used a combination of arguments to rationalize the "inverted-U" relationship frequently observed in the empirical literature, whereby innovative effort or innovative output first increases with concentration and then decreases.

One reason for skepticism about the existence of a direct effect of concentration on innovation is that theoretical arguments justifying such an effect tend to appeal to more fundamental technological or institutional conditions. The empirical literature lends some support to the view that innovation depends on more fundamental conditions. F. M. Scherer (1967) found that the statistical significance of concentration was substantially diminished when a vector of dummy variables categorizing industries by the nature of their technology (chemical, electrical, mechanical, and traditional) was added to the regression. Scherer and others have interpreted these categorical variables as proxies for technological opportunity. Technology classes differ in more than opportunities for technical advance, however; they also differ in the inherent ease of imitation and in the strength of patent protection. The technology class variables used in the literature are thus best interpreted as proxies for both opportunity and appropriability.

Concentration may also proxy for a broader range of industry-specific effects, as suggested in John Scott's (1984) study of *R&D* spending at the business unit level. Using Federal Trade Commission (FTC) data, Scott first replicated the standard inverted-U result, but when fixed effects were added for two-digit industries, as well as for

\*Levin: Professor of Economics and Management, Yale University, New Haven, CT 06520-1972; Cohen and Mowery: Assistant Professors of Economics and Social Science, Carnegie-Mellon University, Pittsburgh, PA 15213. We acknowledge the support of the Division of Policy Research and Analysis, National Science Foundation, and the valuable assistance of Margaret Blair and Andrea Shepard.

companies, the *t*-statistics on the concentration terms dropped by an order of magnitude.

These results suggest that industrial concentration may have no independent significance as a determinant of innovative effort or innovative output. To explore this issue, we attempt to control for systematic interindustry differences in appropriability and opportunity, using data from the Levin et al. survey. We also take account of the possible effects of *R&D* and innovation on market concentration, recognizing that Schumpeter's insights about the role of innovation in determining market structure may be more fundamental than his widely tested hypotheses concerning the feedback from market structure to innovation incentives.

We estimate equations for both *R&D* and innovative output. In the best of worlds, these equations would be embedded in a structural model and derived rigorously. This is the approach taken in related work by Levin and Peter Reiss (1984). We believe nonetheless that there is ample justification for the kind of "pre-theoretical" statistical investigation reported here. Theorists often begin with the "stylized facts." We offer this exploratory data analysis with the hope of providing to other researchers a more accurate assessment of the stylized facts.

## II. Empirical Results

We take as our unit of observation the line of business (*LB*) as defined by the FTC; some *LB*s correspond to four-digit SIC industries and others correspond to groups of four-digit or to a single three-digit industry. As dependent variables, we use the ratio of company-financed *R&D* expenditures to sales from the 1976 Line of Business data and a measure of innovation derived from responses to two questions in the Levin et al. survey. Respondents were asked to score on a seven-point scale the rates at which new products and new processes were introduced into their *LB*s during the 1970's. We measure innovation in each *LB* by summing the mean scores on these two questions. Concentration ratios are taken from the 1972

Census of Manufacturers, and aggregated to the *LB* level when necessary. Since intertemporal changes in concentration and in *R&D* intensity occur slowly, we test each of our reported specifications for indications of simultaneity.

Consistent with the conventional wisdom, *OLS* and *2SLS* regressions of *R&D* intensity on concentration, its square, and a constant term provide support for the inverted-U hypothesis. Since independence of the concentration variables and the disturbance term is decisively rejected, we report the *2SLS* version (with asymptotic standard errors in parentheses):

$$(1) \quad RD/S = 1.810 \\ (1.402) \\ + 0.166C4 - 0.159(C4SQ \times 100). \\ (0.067) \quad (0.068)$$

The coefficients on *C4* and *C4SQ* are both significant at the .01 level (one-tailed tests). Consistent with the previous literature, in which innovative effort typically reaches a maximum at levels of *C4* between 50 and 60, our results indicate that *R&D* intensity is maximized at a *C4* of 52.

We get similar results by regressing our innovation measure on concentration. Here, however, we report *OLS* estimates, since we cannot reject the hypothesis that concentration and its square are independent of the disturbance term:

$$(2) \quad INNOV = 6.013 \\ (0.790) \\ + 0.089C4 - 0.082(C4SQ \times 100). \\ (0.036) \quad (0.036)$$

The coefficients are again significant at the .01 level, and the rate of innovation reaches a maximum at a *C4* of 54.

Controlling for two-digit industry fixed effects, we find that the coefficients of the concentration terms are somewhat reduced in the *R&D* equation, but both remain significant at the .10 level and *R&D* reaches a maximum at a *C4* of 54. Controlling for fixed effects has virtually no impact on the innovation rate equation. The coefficients on

the concentration terms are essentially unchanged, and they remain significant at the .01 level. The rate of innovation is maximized at a *C4* of 58.

To examine whether the effect of concentration on innovative effort and output is more seriously attenuated when direct measures of technological opportunity and appropriability are included in the regressions, we constructed several variables from the Levin et al. survey data. Analysis of the survey data is still in progress, and undoubtedly the quality of the results reported here can be improved once the statistical properties of the survey responses are more fully understood.

Our variables are intended to capture three dimensions of technological opportunity: closeness to science, external sources of technical knowledge, and industry maturity. To measure closeness to science, we used survey responses concerning the relevance of various basic and applied sciences to the technology of each industry. *SCIENCEBASE* was defined as the maximum score received by any one of the eleven fields of science listed on the questionnaire. We also took account of the contributions to an industry's technical knowledge from four external sources: upstream suppliers of raw materials and equipment (*MATERIALTECH* and *EQUIPTECH*, respectively), downstream users of the industry's products (*USERTECH*), and government agencies and research laboratories (*GOVTECH*). Each of these opportunity variables is measured on a seven-point scale. In light of the widely held view that technological opportunity may vary systematically as an industry matures, we also included a variable intended to capture the relative immaturity of an industry's technology. This was operationalized as the percentage of an industry's property, plant, and equipment that was installed within the five years preceding 1976 (*NEWPLANT*), as reported to the FTC's Line of Business Program.

We used two variables to represent appropriability conditions. The Levin et al. survey asked respondents to characterize (on a seven-point scale) the effectiveness of six mechanisms used by firms to capture and

protect the returns from new processes and new products resulting from *R&D* efforts. The listed mechanisms were patents to prevent duplication, patents to secure royalty income, secrecy, lead time, moving down the learning curve, and complementary sales and service efforts. We limit ourselves here to an attempt to discern whether our sample industries had any effective mechanism of appropriation. We therefore operationalize *APPROPRIABILITY* as the maximum score received by any one of the six mechanisms for either process or product *R&D*.

The survey also asked industries to report on the range of imitation costs and time lags for major and minor, process and product, and patented and unpatented innovations. These measures tend to be highly correlated with one another, though they are not highly correlated with *APPROPRIABILITY*. We use here the average time (in months) required to duplicate a patented, major product innovation (*IMLAG*).

Our principal interest in this paper is the robustness of the results that innovative effort and output depend on concentration. In the absence of an explicit structural model, however, prior expectations about the signs of the opportunity and appropriability variables are in some cases ambiguous. Opportunity, as measured by closeness to science and the strength of other external influences on technology, should have a positive effect on innovative output, but to the extent that the efforts of upstream suppliers, downstream users, and the government substitute for an industry's own *R&D* effort, these variables may have a negative sign in the *R&D* equation. Appropriability may also have ambiguous effects on *R&D* incentives, as recent theoretical work has emphasized. Some effective means of appropriating returns is surely required to elicit *R&D* effort. Spillovers among competitors, however, are ambiguous in their effects. They create a disincentive to *R&D* investment by dissipating the innovator's rents, but they also enhance the productivity of *R&D* by strengthening the industry's knowledge base (see Michael Spence, 1984). Thus, *APPROPRIABILITY*, which measures the extent to which an industry has at least one effective means of appropriation,

should have a positive effect on both innovative effort and output. On the other hand, a long imitation lag, which inhibits spillovers, may encourage innovative effort by reducing the disincentive effect, but it may also reduce innovative output, by reducing the productivity of R&D.

Table 1 displays estimates of the R&D intensity equation, alternately excluding and including two-digit industry fixed effects. We again report 2SLS results, because the hypothesis of independence between the concentration terms and the disturbance is rejected by Wu tests. We also found no evidence of heteroskedasticity, despite the

fact that the number of responses to the Levin et al. survey varied across industries.

Comparing Table 1 with (1) in the above text, the coefficients and *t*-statistics on the concentration terms fall by an order of magnitude. There are no anomalous signs; the survey variables as a whole and the opportunity measures in particular are highly significant. Specifically, R&D spending appears to be encouraged in youthful industries where a strong science base is present and where the government makes substantial contributions to technological knowledge. The continued statistical significance of these variables when fixed industry effects are taken

into account suggests that we may have isolated some relevant dimensions of technological opportunity.

Table 2 presents *OLS* estimates of the innovation equation. The *2SLS* estimates were substantively identical, and we found no evidence of simultaneity. Once again, the concentration terms become statistically insignificant at the .05 level once the survey variables are added to the equation, although the linear term is significant at the .10 level. All survey variables have the predicted sign, and they are jointly significant at the .05 level. The two-digit industry effects are jointly insignificant, but their inclusion strengthens the performance of several survey variables: *SCIENCEBASE*, *EQUIPTECH*, and *APPROPRIABILITY*. The signs of the coefficients on *APPROPRIABILITY* and *IMLAG* conform to the expectations discussed above.

### III. Conclusions

In the spirit of "creative destruction," we hope that our findings will at last move the empirical literature beyond the oversimplified propositions that industrial concentration promotes innovative effort and innovative output. To explain interindustry variation in *R&D* incentives and the productivity of innovative effort, we must look to underlying differences in technological opportunities and appropriability conditions. In this paper, we have made only illustrative

use of the Levin et al. data. These new data, and a burgeoning theoretical literature on *R&D* competition in the presence of imperfect appropriability, offer encouragement that a deeper understanding of industrial innovation is within our grasp.

# Patent Licensing and R&D Rivalry

By CARL SHAPIRO\*

It is widely recognized that long-run industrial performance is influenced not only by static efficiency, but also by the rate of technological progress. The single most important factor determining the rate of technological progress in a given industry is the level of industrywide expenditures on research and development (*R&D*) activities.

Another critical factor in determining the rate of technological progress is the rate of *diffusion* of new technologies. The pattern of diffusion influences the pace of technological progress in two ways. First, it directly affects the costs of noninnovating firms and hence the speed with which technological advances are utilized throughout an industry. Second, it feeds back onto the incentives of firms to engage in *R&D*. It is useful to distinguish these two types of effects; I will call the first the *ex post* effect of diffusion and the second the *ex ante* effect.

There are three basic channels through which dissemination takes place: patent licensing, research joint ventures, and imitation. Licensing is a voluntary form of dissemination whereby an inventor can enjoy at least some of the gains to trade from spreading the use of his superior technology. Research joint ventures (*RJVs*) are a way of agreeing to share research results *before* they are realized, a type of "*ex ante* licensing." Imitation is a form of diffusion over which the patentee has little control; noninnovating firms unilaterally appropriate some of the benefits of the discovery.

Intuition suggests that licensing has socially beneficial *ex post* effects, and that it

encourages innovation (*ex ante*) by increasing the rewards to the patentee. Research joint ventures also appear to have socially, if not privately, beneficial effects upon *ex post* dissemination, but it is not clear offhand what effect *RJVs* have on development incentives. Finally, one expects that imitation will have socially favorable *ex post* effects, but will tend to discourage or retard innovation.

In this paper I indicate how the intuition expressed in the previous paragraph stands up under closer analysis. I will discuss the factors that appear most important in determining both the pattern of dissemination of innovations, and the social and private effects of such dissemination. I will emphasize the effects of patent licensing, touching upon joint ventures and imitation along the way. The analysis will be conducted in the context of an oligopolistic industry. An oligopolistic setting is the natural one on which to focus, as patents, by their very nature, create market power, and as many progressive industries have concentrated market structures.

## I. Licensing of a Given Innovation (*Ex Post* Licensing)

Once an innovation has been patented, there are natural social and private incentives to see that it is employed widely in situations where it will lower production costs. With perfect information, and no transactions costs, therefore, we would expect licenses to be issued to all firms that could benefit from the improved technology.

The argument is straightforward: there are gains to trade from licensing, and the patentee can design contracts that split these gains between itself and potential licensees. For example, it could charge a royalty per unit of output that just equals the reduction in per unit costs that the licensee achieves on account of the new technology. This would leave the licensee indifferent between licens-

\*Princeton University, Princeton, NJ 08540. The reader will soon observe my debt to my colleague, Michael Katz, with whom I have done much of the work on patent licensing described herein. I thank Nancy Gallini for extensive comments on related work, Richard Caves for informing me about patent licensing in practice, Paul David, Avinash Dixit, Gene Grossman, and Ken Judd for comments and suggestions on a draft of this paper, and Steve Salop for general inspiration.

ing and not, and let the licensor enjoy the gains from the licensee's improved efficiency. While the licensor appropriates all of the gains to trade with this particular contract, there are clearly other contracts that split the gains more equally.

What will the (privately) *optimal* licensing contract look like? In general, patent licensing contracts can be designed to implement perfectly the monopoly (fully collusive) outcome. Doing so will maximize the pie that is to be split between the licensor and any licensees. To achieve the collusive outcome, it is sufficient to consider two-part tariff contracts consisting of a fixed fee,  $F$ , and a per unit royalty rate,  $r$ .

This general principle is most transparent in the context of a single firm licensing its patent to its lone rival. The idea is that the licensing firm can control its rival's marginal cost, and hence can manipulate its rival's behavior (reaction curve), through the use of the per unit royalty rate. With an appropriate choice of royalty rate, the collusive outcome can be achieved. Doing so is simply a matter of computing the licensee's reaction curve, given the royalty rate, and then choosing that rate so that the licensee's reaction curve intersects that of the licensor at a point where industry output is at the monopoly level.

Two rivals (with or without innovations) alternatively could design a cross-licensing agreement whereby each would pay the other a royalty per unit of output, ostensibly for the right to use the other's technology. By imposing a "tax" on each other (or by writing pricing or territorial restrictions into the cross-licensing contract), the firms could again achieve the fully collusive outcome. A cross-licensing contract may be required to achieve the fully collusive outcome if the firms produce different products or are otherwise heterogeneous.

The reader may be surprised that even a minor innovation can markedly alter the industry's final behavior. Indeed, a sham innovation can be "licensed" to facilitate collusion! How is this possible? For such an "innovation," the licensing contract would have a large royalty rate and a negative fixed fee. That is, the licensor would reduce its rival's output by imposing a "tax" of  $r$  per

unit, and then compensate the licensee for this tax with a negative fixed fee (i.e., a side payment). In the extreme case, this licensing contract would be equivalent to a bribe paid by the licensor to induce the licensee to exit the industry.

Such a side payment, in exchange for which the licensee would reduce its output, is likely to be illegal under the antitrust laws, and for a good reason! So, a reasonable constraint to put on the two-part tariff contract is that the fixed fee be nonnegative. Equivalently, the licensor cannot charge a royalty rate in excess of the per unit savings the licensee enjoys with the new technology; the licensing contract cannot raise the licensee's marginal (production plus royalty) costs. With this restriction, the optimal contract would set the royalty rate as high as possible (i.e., at the per unit cost savings afforded by the new technology), and have no fixed fee.<sup>1</sup>

My analysis so far indicates that licensing contracts should arise for any innovation for which the transactions costs are low, and two-part tariff contracts can be written. Yet licensing among rivals is not often observed in practice. Besides the direct costs of technology transfer, there are three information problems that may limit the firms' ability to achieve the licensing gains to trade. First, there may be asymmetric information regarding the value of the license; this may undermine the parties' ability to strike a licensing deal. Second, the innovator may find it difficult to let others use his invention without giving them useful information in the ongoing competition to acquire additional patents.<sup>2</sup> Third, it may be costly or

<sup>1</sup> Nancy Gallini and Ralph Winter (1984) and Morton Kamien and Yair Tauman (1984) analyze licensing contracts of this form. Such a contract gives all of the licensing gains to trade to the licensor. Depending upon the bargaining power of the two parties, a lower royalty may arise. According to Richard Caves et al. (1983), licensors enjoy an average of about 40 percent of the gains to trade from licensing.

<sup>2</sup> It may be difficult to design a contract that prevents such usage of the information. In a survey reported by Caves et al., 43 percent of licensing agreements contained a "technology flowback" provision, which required the licensee to share any advances or improvements in the licensed technology with the licensor. For

impossible for the licensor to monitor the licensee's output so as to charge per unit royalties. The first two considerations are beyond the scope of this paper; I shall, however, report some results relating to the third.

If per unit royalties cannot be levied, the licensor must balance off two effects of a fixed fee license: such a license spreads the use of the improved technology, but it also makes the licensee a more vigorous rival. We would expect a license to be issued if and only if doing so raises the joint profits of the licensor and the licensee (in which case they could split the gains in some fashion). In the duopoly context, joint profits are industry profits, so the question of whether licensing will occur reduces to the question of how lowering the licensee's costs influences industry profits.

In this context, Michael Katz and my paper (1984a) shows that drastic innovations (those allowing the patentee to enjoy a monopoly) will not be licensed, and that an innovation that is nearly drastic will also not be licensed. On the other hand, a small innovation by one of two equally efficient firms will be licensed if and only if  $x p''(x)/p'(x) > -2$ , where  $p(x)$  is the industry demand curve, and  $x$  is the initial industry output level. For linear demand ( $p'' = 0$ ), therefore, small innovations will be licensed. This suggests that the neglect of patent licensing in the existing R&D literature is unfounded: even under stringent constraints on the licensing contract, licensing is often profitable. This result would only be strengthened with more than two firms, as the other firms would reduce their output in response to such a licensing agreement.

When licensing cannot raise the licensee's marginal costs, as is the case for fixed fee licensing, it will tend to increase the licensee's output, and total industry output as well. So, consumers will benefit from patent licensing. In the duopoly context, this implies that the firms' private incentives to license are less than the social incentives. In an oligopoly

context this conclusion is not warranted, however, as the firms that are not parties to the licensing contract will typically be made worse off on account of the license. A final welfare point is that (fixed fee) licensing is not always socially beneficial. (See Katz and myself, 1984a.) If the licensor is more efficient than the licensee, even with the new technology, it may be optimal for the licensee to produce using the old technology. This will definitely be the case if the licensee would be close to shutting down even with the license. The reason is that licensing to the less efficient firm diverts output from the more efficient firm under a variety of oligopoly solution concepts. So, even *ex post*, and even disallowing per unit royalties, mandatory licensing may be undesirable.

So far I have discussed mainly one duopolist licensing its innovation to its rival. A new set of issues arises when one considers the optimal way for an innovator to license his patent to a subset of (downstream) oligopolists. The added richness arises because one firm's willingness to pay for a license depends upon the set of other firms that are also purchasing licenses. This *interdependence of demands* is a consequence of the fact that the new technology reduces each licensee's marginal cost, and hence alters its reaction curve in the final pricing or output game.

In general, the value to a given oligopolist of obtaining a license to a product or process innovation depends upon the set of the firm's rivals purchasing licenses. For process innovations in a homogeneous good industry, obtaining a (fixed fee) license is *less* valuable to a given firm if more of its rivals have done so. If the license permits the firm to adopt a new industry standard, however, it may be *more* valuable if more rivals have licenses. Both the optimal licensing scheme and the pattern of dissemination to which it leads depend heavily upon whether the demand interdependencies are "negative" or "positive."

Morton Kamien and Yair Tauman have analyzed licensing in the context of a symmetric, Cournot oligopoly with constant average costs facing a linear demand schedule. They consider fixed fee contracts and pure per unit royalty contracts. The optimal

---

further information on patent licensing contracts in practice, including the use of fixed fees vs. per unit royalties, see Charles Taylor and Z. A. Silberman (1973).

royalty contract charges a royalty that just equals the per unit cost savings from the new technology (as noted above in a duopoly context). With this contract, each licensee's downstream behavior is unaffected by the contract, and the demand interdependencies vanish. Kamien and Tauman demonstrate that fixed fee contracts are more profitable for the patentee than are royalty contracts. The reason is that they *do* exploit the demand interdependencies, leaving the firms *worse off* than they were prior to the innovation.

Restricting attention to fixed fee licensing, Katz and I (1984b) have extended this analysis in a number of directions. We consider very general downstream oligopoly cost, demand, and behavioral conditions, and general auction schemes for selling the licenses. Furthermore, we look both at the case where the patent is owned by an independent (upstream) research lab, and the case where the patent is jointly owned by a subset of the (downstream) oligopolists, a research joint venture. One principle that emerges is that it is generally *not* optimal to sell the licenses using the conventional price system. That is, it is not optimal (for the patentee) simply to set a price per license and let the firms each decide whether or not to purchase a license at the set price.

The reason the price system does not maximize the seller's revenues is that it has no built-in ability to "threaten" the buyers. When one buyer decides not to purchase a license, his decision has no effect on the purchase pattern of the other firms. So, under the price system, a buyer can take as given the number of others that will purchase licenses. If, in equilibrium,  $k$  of the  $n$  oligopolists purchase licenses, the most that each buyer will pay for a license is  $W(k) - L(k - 1)$ , where  $W(k)$  is the payoff to a license holder (a "winner"), gross of any license fees, if  $k$  licenses are sold, and  $L(k)$  is the payoff to a firm without a license (a "loser") if  $k$  are sold.

Consider the alternative "quantity" system, whereby the seller announces that  $k$  licenses are to be sold to the  $k$  highest bidders. Then, a firm knows that  $k$  licenses are sure to be sold, and it will pay up to

$W(k) - L(k)$  for one. So long as a non-licensee is worse off the more of its rivals purchase licenses (i.e., so long as  $L(k)$  is strictly decreasing with  $k$ ), the quantity system will yield the seller higher revenues.

Katz and I (1984b) characterize the inventor's optimal licensing strategy within the following class of sales mechanisms: the inventor can run an auction in which there are  $k$  licenses available, and these will be sold to the  $k$  highest bidders (at their bidding prices), subject to a minimum bid. Making licenses available for all potential buyers at a minimum bid  $b$  amounts to using the price system with a price of  $b$  per license.

When the inventor employs the optimal auction scheme to sell the licenses, all of the firms that are not members of the joint venture (which is *all* of the oligopolists in the case of the independent research lab) are made worse off on account of the innovation. In terms of the notation introduced above, the oligopolists' pre-innovation payoff levels are given by  $L(0)$ ; after the innovation, the firms earn the lower payoff of  $L(k)$  if  $k < n$  licenses are sold.<sup>3</sup> Essentially, the innovator appropriates some of the oligopolists' initial property rights to their oligopoly profits, by threatening them with the lower profit level that they would earn if some of their rivals obtained licenses and they did not.

Katz and I (1984b) also show how the pattern of ownership of the patent influences its dissemination. In the class of mechanisms described above, larger joint ventures have an incentive to issue fewer licenses. So, the notion that *RJVs* promote dissemination may be unfounded. Even if the joint venture is contractually required to issue licenses to all of its members, the independent lab will issue more licenses than will a small joint venture.<sup>4</sup>

<sup>3</sup>If it is optimal to issue licenses to all  $n$  of the oligopolists, then the inventor *will* employ the price system, and each firm's payoff will be  $L(n - 1)$ .

<sup>4</sup>Of course, large joint ventures will disseminate the innovation more widely if they must give it to all of their members on a royalty free basis. Also, if entry fees can be charged in the license auction, ventures of all sizes will have incentives to issue the number of licenses that maximizes industrywide oligopoly profits.

If one permits the patent holder to issue two-part tariff licensing contracts, and to use a general auction mechanism with entry fees, the industry will duplicate the fully collusive outcome under the new technology. The patent holder will appropriate all of these profits for himself, and the oligopolists (not in the venture) will earn zero profits, after licensing royalties are accounted for. So licensing, while spreading the use of the new technology, may lead to less competitive industry behavior.

## II. The Effect of Licensing on Development Incentives (*Ex Ante* Effects)

If one considers a single (potential) inventor investing resources to develop a given innovation, it is clear that the possibility of licensing can only increase the value that the inventor places upon developing the invention. After all, he can always refrain from licensing, and often will find the payoff to innovating higher on account of licensing.

In addition to increasing the (single) inventor's development incentives, licensing may make these incentives socially excessive. There are two reasons why this may happen. First, there are private returns to patenting, namely the induced monopolization of the downstream industry through the use of per unit royalties, which are not social returns. This reward for the inventor may be viewed as a return to the ability to write contracts among the oligopolists that raise their perceived marginal costs. Second, even without the use of such royalties, the private returns to the inventor include the reduced profits of the downstream oligopolists, as noted above. These are transfers, not social benefits arising from the innovation.

When competition to develop an innovation is considered, the effect of licensing upon R&D is not necessarily positive. First, in the context of multiple innovations, licensing may be used to strategically deter a rival's R&D. Nancy Gallini (1984), and Gallini and Ralph Winter, show that such strategic (*ex ante*) licensing is more likely to occur when the firms' costs differ widely.

Even *ex post* licensing need not encourage R&D in a patent race context. While it is

true that licensing increases the returns to winning the patent, it also increases the returns to *not* winning the patent. Specifically, a firm may know that it will become a licensee if it loses the patent race. So long as the licensor does not appropriate all of the gains to trade from licensing, the expectation of being a licensee will dampen a firm's incentives to win the patent. Clearly, the way in which the gains to trade from licensing are split between the licensor and the licensee is a critical factor influencing firms' incentives to develop.

In a duopoly patent race model, Katz and I (1984c) show that the possibility of (*ex post*) licensing can completely alter the nature of dynamic rivalry. Specifically, each firm may prefer losing the race to winning it. Likewise, each firm may *benefit* when its rival patents. The former will occur if the development and patenting costs (which are incurred only by the patentee) are large, and the latter if the licensee enjoys substantial benefits on account of the licensing contract. In such cases, the race takes on the character of a waiting game: each firm hopes that its rival will develop the innovation, which is like a public good for the two firms. (The same effect can also arise due to imitation rather than licensing.) Licensing may delay innovation, as each firm is more content to wait, lose the race, and become a licensee.

## III. Conclusion

Patent licensing, research joint ventures, and imitation have significant effects on both the rate of (*ex post*) diffusion of new technologies, and on private firms' (*ex ante*) incentives to develop such technologies. Recent work analyzing the impact of these channels of dissemination indicates that these *ex ante* and *ex post* effects interact in surprising ways. For example, while licensing contracts serve a useful function of spreading the use of superior technologies, they may be used to facilitate collusion. While patent licensing increases the value of winning a patent, it also increases the value of losing a patent race, and thus need not encourage innovation. And, while research joint ventures avoid duplication of research efforts

(see Katz, 1984, or Gene Grossman and myself, 1984), they may inhibit diffusion and reduce development incentives (Katz and myself, 1984b).

While much progress has been made in understanding dissemination and its role in the process of technological change, large gaps remain in our understanding. Most notably, more work is needed to understand the information problems facing patent licensing contracts, and to understand the effect of research joint ventures on the pace of technological advance.

## Nominal Wage-Price Rigidity as a Rational Expectations Equilibrium

By COSTAS AZARIADIS AND RUSSELL COOPER\*

Most recent studies of macroeconomic behavior fall into one of two categories. The first, often called the equilibrium business cycle approach, stems from the fundamental contribution of Robert E. Lucas (1972), and related work by Thomas Sargent and Neil Wallace (1975) and many others. These studies espouse the view that a positive correlation between output and the stock of paper assets can arise if households are unable to identify the source and, therefore, the permanence of price movements.

Employment and output responses in this view are driven by the intertemporal substitution effect, especially the substitution of current leisure for future consumption. Since cyclical fluctuations in employment are large relative to the corresponding real wage movements, substantial wage elasticity of labor supply is required to validate these models.

The equilibrium approach to business cycles implies certain restrictions on the conduct of monetary policy. In particular, rational expectations undermine the ability of the monetary authority to influence economic activity in a systematic manner; see Sargent-Wallace for an example.

Sticky wages and prices are the cornerstone of an alternative description of macroeconomic behavior. Rooted vaguely in Keynes, and more firmly in the "dual decision hypothesis" of Robert Clower (1984), this approach studies equilibria with quan-

tity rationing; see Edmond Malinvaud (1977). The rationing story lacks a precise specification of the *source* of price stickiness, offering very little guidance about the eventual causes of price change.

Considerable efforts were made in the 1970's to fill this lacuna in Keynesian macroeconomics. Beginning with work by Martin N. Baily (1974) and others, the implicit contracts literature focused on the incomplete insurability of human capital. Unable to find insurance against fluctuations in labor income elsewhere, workers demand insurance from those best placed to observe labor income—their own employers. Both wage inflexibility and layoffs, then, can be viewed as an outcome of a joint insurance-employment relationship between workers and firms; see Azariadis (1975).

Critics like George Akerlof and Hajime Miyazaki (1980) soon discovered that the original contracting models could not produce layoffs without prohibiting severance pay or otherwise limiting the terms of the contract. Others pointed out that these models were determinedly microeconomic, offering few insights into the stickiness of *nominal* wages or the effectiveness of stabilization policy.

Two quite distinct lines of research developed out of the original implicit contract ideas. One focuses on asymmetric information and implementability (see the *QJE* 1983 Symposium for original work and the review article by Oliver Hart, 1983) as a means of driving a wedge between the *ex post* marginal rates of substitution of the contractants. Under some technical assumptions, the outcome is "involuntary" underemployment or unemployment.

We are most concerned here with the other line of research, which sought to fit labor or

<sup>†</sup>*Discussants:* Guillermo Calvo, Columbia University; Jo Anna Gray, Washington State University.

\*Department of Economics, University of Pennsylvania, Philadelphia, PA 19104; and Cowles Foundation, Yale University, New Haven, CT 06520, respectively. We thank Takatoshi Ito for useful comments.

commodity contracts into full-blown macroeconomic structures; see Stanley Fischer (1977), and Arthur Okun (1981). These authors apparently took their cue from the insurance arrangements stressed in the implicit contracts literature. Just as in the rationing approach mentioned above, the macro contracts literature does not fully derive the structure of trades from first principles; it asserts instead that money wages are predetermined and that employment is set by labor demand. This rule (see Robert Barro, 1977) is not in the best interest of the contractants for it requires laborers to be permanently off their offer curve. Consequently, macroeconomic contract models are not an entirely reliable guide for policy evaluation.

As we take stock of matters, it seems to us that the time is ripe to assess what role contracts play in macroeconomics. An ideal outcome would be a coherent story of money-wage stickiness, and of output response to stabilization policy.

This paper distills recent research, by ourselves and others, that pursues that ideal without quite reaching it. The presentation here favors intuition over technical detail as much as possible. The next section, in particular, discusses examples of intertemporal economies that possess competitive rational expectations equilibria in which wages and prices are predetermined, output is sensitive to policy shocks, and markets clear. Section II reports on the existence of Nash equilibria with similar properties when producers set both prices and wages.

# I

We outline here some rational expectations equilibria of an overlapping generations economy that begins at time zero and goes on forever. The beginning of each time period  $t = 0, 1, \dots$ , coincides with the appearance of a generation, labeled "generation  $t$ ," that consists of  $2N$  individuals, all of whom survive for two full periods: "youth" and "old age." Individuals specialize over their life cycle, participating in the production of a single, perishable commodity when young, saving their entire factor rewards to purchase a paper asset called "money," and

using their assets in old age to finance the consumption of the same commodity they helped produce in youth. We assume that no endowments exist of this valuable commodity—it must be produced before it is consumed.

Every generation consists of  $N$  identical, risk-neutral workers, and  $N$  identical, risk-neutral entrepreneurs. Each worker is endowed with  $\bar{n} > 0$  units of divisible leisure in youth, and with a utility function  $c_{t+1} - kn_t$ , over old age consumption ( $c_{t+1}$ ) and youthful work ( $n_t$ ). The parameter  $k$ , interpreted here as a reservation wage, is the same for all workers in all generations, and lies in the interval  $(0, 1)$ .

Entrepreneurs own in youth the constant-returns technology  $y_t = n_t$ , the only means of production in this society. Denoting by  $p_t$  the money price of goods and by  $w_t$  the money wage, it is clear that a generation  $t$  entrepreneur consumes in old age  $(p_t - w_t)n_t/p_{t+1}$ .

Money is printed by the government to finance purchases of goods from private sellers. Real per capita government purchases are an independent, identically distributed random variable,  $\tilde{g}_t$ , with a probability measure defined over the positive interval  $[a, b]$ , and expected value  $\mu > 0$ . We assume  $b < \bar{n}$ , that is, government purchases never exceed the productive capacity of the economy.

If  $M_t$  is the nominal stock of money in period  $t$  and  $m_t = M_t/p_t$  is its purchasing power, the government budget constraint can be written in either of the following two forms:

$$(1) \quad \begin{aligned} p_t g_t &= M_t - M_{t-1} \\ p_{t-1}/p_t &= (m_t - g_t)/m_{t-1}. \end{aligned}$$

All agents, including the government, are wage and price takers. Commodities purchased by the government are used up with no effect on any household's preferences over private goods.

The constant returns to scale assumption means that the demand for labor (and supply of goods) is zero if  $p_t < w_t$ , and infinity if  $p_t > w_t$ . Competitive equilibrium is trivial in the former case, and nonexistent in the latter.

We focus therefore on the case  $p_t = w_t$ , which makes employment supply determined. In particular,  $n_t \geq 0$  if the expected purchasing power of wages satisfies

$$(2) \quad w_t E_t(1/p_{t+1}) = p_t E_t(1/p_{t+1}) \geq k.$$

Also,  $n_t = \bar{n}$  if (2) holds as a strict inequality. Here  $E_t$  is the expectations operator conditional on all events up to, and including, period  $t$ .

Equilibrium in the goods market requires goods supply  $n_t$  to equal goods demand. Demand is simply the real value of existing money balances  $m_t$ , held by retired individuals and by the government.

Combining the market-clearing condition  $m_t = n_t$  with relations (1) and (2), we see readily that every competitive equilibrium satisfies

$$(3) \quad E_t m_{t+1} \geq k m_t + \mu,$$

with  $m_t \leq \bar{n}$ , and  $m_t = \bar{n}$  if (3) is a strict inequality. As one may guess, inequality (3) admits many equilibria, the most interesting of which we present below (see also Roger Farmer and M. Woodford, 1984).

One class of equilibria worth noting features *flexible prices and predetermined quantities*: current events are reflected in current equilibrium prices but not in current equilibrium quantities. A member of this class is the full-employment equilibrium ( $p_t = w_t$ ,  $p_{t-1}/p_t = 1 - g_t/\bar{n}$ ,  $m_t = \bar{n}$ ) for all  $t$ , which is easily seen to satisfy relations (1) and (3) provided that

$$(4) \quad \mu \leq (1 - k)\bar{n}.$$

A second class of equilibria has *predetermined prices and flexible quantities*: current events influence current quantities but not prices. One member of this class (and the only one existing in our simple economy) is ( $p_t = w_t$ ,  $p_{t-1}/p_t = k$ ,  $m_t = k m_{t-1} + g_t$ ) for all  $t$ . This one, too, is consistent with relations (1) and (3). The implied path of output

$$(5) \quad m_t = k^t m_0 + \sum_{s=0}^{t-1} k^s g_{t-s},$$

stays in the interval  $[a/(1-k), b/(1-k)]$  if it begins there, that is, if the initial parameter  $m_0$  lies in that interval. Therefore, a predetermined wage-price equilibrium exists if

$$(6) \quad b \leq (1 - k)\bar{n}; \quad a > b(1 - k).$$

That is, if the aggregate demand for goods never exceeds the economy's productive capacity, and output never falls short of government consumption.

Both the full-employment and the underemployment equilibria are full rational expectations equilibria in cleared markets. But they differ substantially in what they predict about the economic consequences of policy shocks. The full-employment equilibrium has very classical properties: prices are flexible and complete crowding-out obtains. Government expenditure ( $g_t$ ) displaces private consumption ( $\bar{n} - g_t$ ) one-for-one.

The underemployment equilibrium possesses Keynesian features: predetermined wages and prices; no crowding-out in the short run, since private consumption is predetermined; and a long-run "multiplier" of  $1/(1-k)$ , which exceeds unity. To understand the last assertion, replace the random variable  $\tilde{g}$  by  $\lambda \tilde{g}$ , where  $\lambda$  is a positive constant. Then, clearly, the output path will stay in the interval  $[\lambda a/(1-k), \lambda b/(1-k)]$  if it begins there.

Looking back at inequalities (4) and (6), one sees that neither equilibrium exists if government purchases are "too large" on average; in particular, a predetermined price-and-wage equilibrium is impossible if government purchases are "too dispersed." Wage rigidity is not a frequently observed phenomenon when macroeconomic policy is highly uncertain.

Full-employment equilibria here yield the highest possible consumption, net of the disutility of work, and therefore are superior to underemployment equilibria in the familiar sense of first-degree stochastic dominance. Nevertheless, full employment is but one of many possible equilibria in this model economy. The underdeterminate nature of equilibrium is a weakness of our model, and perhaps of actual intertemporal economies as well. To pin down the equilibrium, we need

an additional restriction, for example, a description of how a hypothetically independent monetary authority would react to government spending. Suppose, in particular, that the authority follows the rule

$$(7) \quad M_t - M_{t-1} = (p_{t-1}/k)g_t.$$

Then predetermined prices are validated and a predetermined quantity equilibrium is no longer tenable.

## II

The above analysis suggests that contracts are not necessary for the existence of equilibria with predetermined wages and prices. In both the predetermined-price underemployment equilibrium and the flexible-price full-employment equilibrium, workers' old age consumption was independent of shocks in their youth. Hence, even if worker's preferences were strictly concave functions of  $c_{t+1} - kn_t$ , labor contracts could not improve the sharing of consumption risks. There are, of course, other spot equilibria in the model of the previous section for which old age consumption does depend on shocks in youth; introducing contracts will generally affect these equilibria in a way that need not concern us here.

A more interesting question is whether the old age consumption of risk-averse workers can be set independently of the government policy shocks realized in their *old age*. Since labor contracts can only protect workers against events in their youth, we consider both commodity and labor contracts to explore fuller lifetime insurance opportunities. This represents a merger of labor contracts with the "customer market" approach advocated by Okun. Using a variant of the model outlined above, we explore whether nominal wage rigidities may be the outcome of a game between wage-setting and price-setting agents.

Assume workers have lifetime utility functions of the form  $u(c_{t+1} - kn_t)$  where  $u$  is increasing and strictly concave. Entrepreneurs of generation  $t$  are still risk neutral, but they are assumed to be born at the beginning of period  $t - 1$  and live for three

full periods, producing in the middle one and consuming in the last one. They are endowed with  $\bar{e} > 0$  of commodities (or leisure) in middle age;  $\bar{e}$  is also the fixed cost of operating a firm.

The source of uncertainty here is slightly different from our first model. The period  $t$  money supply is  $m_t = m_{t-1}\tilde{x}_t$  where  $\tilde{x}_t$  is a random variable with a stationary distribution over the interval  $[1, \bar{x}]$ . All money creation finances government purchases.

We assume that all *ex post* trades are mediated through contracts. A generation  $t$  entrepreneur is involved in *three* contracts. First, he supplies commodities to both old (generation  $t - 1$ ) agents and the government in period  $t$ , under a price schedule established in period  $t - 1$ , before  $x_{t-1}$  is realized. Second, he signs a labor contract with generation  $t$  workers to produce the commodities demanded by the previous generation given the firm's price schedule. Finally, as a future consumer, the entrepreneur makes purchases from a generation  $t + 1$  firm. A generation  $t$  worker faces a period  $t$  wage schedule and a period  $t + 1$  price schedule at the very beginning of period  $t$ , before  $x_t$  is realized. This timing provides the maximal scope for insurance.

Firms must also coordinate output and employment levels across their commodity and labor agreements. We assume that firms meet all *ex post* demand given their pricing policy, so that demand determines employment. Hence fluctuations in demand generate movements in output and employment. The magnitude of this correlation depends upon the sensitivity of prices to past and present changes in the stock of money.

Consider a game between firms (both within and across generations) where the strategic variables are wage and price schedules. Workers and risk-averse consumers are nonstrategic players who exchange with a firm offering the most attractive wage and price schedules. The government and old age entrepreneurs purchase equal amounts from those firms that charge the lowest expected price. An equilibrium is then a sequence of wage and price functions  $(w_t, p_t)$ , dependent on events up to and including period  $t$ , which constitute a symmetric Nash equi-

librium in the game described above. Output in such an equilibrium is bounded by the productive capacity of the economy. Cooper (1984) discusses the detailed conditions for such equilibria in a closely related model.

Here we explore the possibility of a Nash equilibrium with wages and prices independent of policy shocks. Since realizations of  $x_t$  are public information,  $w_t$  will generally be indexed if  $p_{t+1}$  reflects  $x_t$ . Hence, we are searching for an equilibrium where both  $w_t$  and  $p_{t+1}$  are independent of  $x_t$ . Consider  $w_t = \alpha M_{t-1}$  and  $p_{t+1} = \beta M_{t-1}$ , for all  $t$ , as a candidate equilibrium. If  $\alpha/\beta = k$ , workers receive full insurance. The parameters of the contract can be set so that the expected consumption of a generation  $t$  entrepreneur satisfies  $E_{t-2} c_{t+1}^F = \bar{e}$  for all  $t$ . We expect this to emerge from the competition among firms.

A key issue here, as in the previous section, is the feasibility of such an equilibrium. Since quantities are demand determined, total employment (and hence output) in period  $t$  equals  $M_t/p_t$ . With  $p_t = \beta M_{t-1}$ , the maximal level of possible demand is  $(\bar{x})^2/\beta$ . Since the productive capacity of the economy is  $N\bar{n}$ , this predetermined wage/price equilibrium will exist iff  $N\bar{n} \geq (\bar{x})^2/\beta$ , where the parameter  $\beta$  turns out to be independent of  $\bar{x}$  and  $N\bar{n}$ . This condition reinforces our intuition that predetermined wage and price equilibria will not exist if policy is too "variable."

# Wage Flexibility in the United States: Lessons from the Past

By DANIEL J. B. MITCHELL\*

Recently, various macroeconomic arguments for promoting wage flexibility and/or gain-sharing plans (such as profit sharing) have been developed. This paper explores why—despite such arguments—wage flexibility declined historically and profit-sharing-type arrangements have not covered most workers.

## I. Past Wage Flexibility

In another paper (forthcoming), I have contrasted wage setting in the 1920's with that of the post-World War II period. During the 1920's and early 1930's, the U.S. Bureau of Labor Statistics published an incomplete sample of reported wage-change decisions at the establishment level. Perhaps the best way to summarize the results is to direct attention to Table 1, which presents the distribution of manufacturing wage-change decisions during 1924 and 1925, years in which consumer price inflation was, respectively,  $-.2$  and  $+4.0$  percent on a December-to-December basis.

The table shows a wide array of wage-change decisions ranging from cuts of over 20 percent to increases of similar magnitude. This dispersion of decisions is remarkable by post-World War II standards. Moreover, the postwar evidence suggests that nominal wage cuts are a rarity, even in periods of low inflation. When they do occur, as in some recent union concessions, the cuts result from a painful negotiations process against a background of threatened or actual mass layoffs.

By the 1920's, many features of modern corporate enterprise were present. But unions were of little significance in most sectors, including manufacturing, the result of a sustained "open shop" campaign by employers

after World War I. There was little labor market intervention by government. Workers resented wage cuts—during periods of generalized wage cutting such reductions became important causes of strikes—but employers implemented them anyway. And when employers did not want to take the blame for wage cuts, they used "company unions" to "negotiate" reductions (Robert Dunn, 1927, pp. 21–23).

In short, in the absence of unions or other institutional constraints, the implicit contracts offered by employers in the 1920's provided substantially more wage flexibility than existed after World War II. The wage-setting mechanisms of the 1920's did not approach the flexibility of a classical auction market, a fact of some comfort to implicit-contract theorists. However, it is unclear that one needs to go much beyond simple explanations of how wage cuts (or even relative wage slippage) would lead to worker resentment and management caution.

## II. Why Did Wage Flexibility Diminish?

Implicit contract theories have emphasized worker risk aversion and/or turnover costs to explain wage unresponsiveness. Perhaps risk aversion and turnover costs increased after the 1920's, but the most significant changes that occurred involved unionization, new public policies, and changing social expectations.

In an important forthcoming book, Sanford Jacoby documents the development of internal personnel policy of American employers during the first half of this century. Jacoby points out that until World War I, employers were content to leave personnel policy to foremen. But during World War I, the budding field of personnel management—linked to other social welfare movements—took root. Employers created personnel departments to handle industrial relations on a centralized basis and to engage in "welfare work" among their employees. Their impetus

Note: Shown in percent. Details need not sum to totals due to rounding. Unit of observation is the establishment.

<sup>a</sup>Less than 0.5 percent.

was a combination of war-related labor shortages and rapid growth in unionization which reflected various government policies aimed at achieving industrial peace and uninterrupted war production.

During the 1920's, in contrast, the labor shortage ended and government withdrew from the labor market. Unions were defeated as a threat. Firms downgraded their personnel departments, returned authority to foremen, and lost interest in workplace changes advocated by softminded reformers. When the union threat (supported by New Deal policies and later World War II controls) reappeared, the process reversed. Firms upgraded their personnel departments, downgraded foremen, and undertook various "progressive" personnel policies.

With the Great Depression came a purchasing power theory of wages that had a profound effect on public policy. Under this theory, depressions occurred if wages received too small a share of income. Low wages led to underconsumption. Maintaining wages, not cutting them, was seen as the appropriate policy for business downturns.

President Hoover urged firms not to cut wages at the onset of the depression (National Industrial Conference Board, 1932,

p. 3). And until 1931, his injunction seemed to have some effect. Pre-New Deal legislation, such as the Davis-Bacon Act (1931), reflected the wage-underconsumption idea. But the New Deal itself represented the high point of this theory, a theory supported by prominent economists of the time such as Paul Douglas (1935, pp. 212; 223-26), later a president of the American Economic Association.

The centerpiece of the early New Deal was the National Industrial Recovery Act (1933) that sought to boost business confidence by applying cartel-type codes on an industry basis. Code labor provisions set minimum wages, provided guides to wage differentials, and regulated other workplace conditions. Collective bargaining was also encouraged. At the bottom of a severe depression, a rash of wage *increases* suddenly developed as the result of these codes and wage cuts became the exception.

Although the NIRA was declared unconstitutional in 1935, elements were retained in such laws as the Wagner Act of 1935 (that contains the wage-underconsumption theory in its preamble) and the Fair Labor Standards Act (1938). Unemployment insurance (*UI*), established by the Social Security Act of 1935, is premised on layoffs rather than wage cuts as the response to falling demand. And since *UI* is not fully experience rated, it contains a net subsidy to layoff adjustments. Wage cuts can also have an adverse effect on future Social Security benefits received by workers. And they can adversely affect benefits to be paid under private (tax-code supported) pension plans.

More generally, the social ethos was changed by the depression. "Good" employers did not cut wages. To do so invited employee resentment and, possibly, unionization. Layoffs by seniority, tightly enforced in the union sector, less rigidly followed but still influential in the nonunion sector, became the basic mode of adjustment. And lest employers slip, they now have the Age Discrimination in Employment Act (1967, 1978)—age and tenure are highly correlated—to remind them to respect seniority.

After the 1940's, government programs created a "third wave" of pressures strengthening centralized employer personnel poli-

cies. The tax code was amended to favor a variety of employer-provided fringe benefits requiring expertise in administration. In the 1960's various federal and state "equal employment opportunity" programs further elevated the control of personnel departments. And the 1970's saw new legislation in occupational safety and health, pension plan regulation, and other areas which continued the trend. Centralized personnel bureaucracies are not conducive to flexible wage decisions.

In short, there is considerable evidence that what changed after the 1920's was first the union threat, and second, a variety of public policies and expectations. Modern unionized firms exhibit wage unresponsiveness because of strategic factors (for example, strike costs) involved in negotiations—that lead to averaging out the business cycle under long-term contracts—and because "median voter" tastes and seniority systems lead to a preference for layoffs rather than wage cuts. Nonunion firms have historically been concerned about the union threat and have evolved strong personnel bureaucracies to administer "unionese" employee-welfare programs.

### III. Why Don't We Have More Profit Sharing?

The tendency toward unresponsive wage rates could be overcome by gain-sharing arrangements such as profit sharing. But if profit sharing has macroeconomic benefits, it will be used less than is socially optimal since employers (and unions) will not take account of the externalities. Certainly, current wage practices are far removed from a gain-sharing economy.

Although externalities will be ignored, employers (and unions) might establish profit sharing based on private incentives. Why haven't these incentives inspired more widespread use of profit sharing? The answer cannot be that the technology is new. Profit sharing reportedly began in France in the 1840's; then spread to other countries (Lyle Cooper, 1934). The first profit-sharing plan in the United States appeared in 1867; by 1916, the Bureau of Labor Statistics undertook a study of profit-sharing plans and

found a total of sixty in operation covering about 30,000 workers (Boris Emmet, 1917). Profit sharing provoked academic interest as early as 1887, when a debate on the issue appeared in the *Quarterly Journal of Economics* (Richard Aldrich; Franklin Giddings), and continued into the 1920's (F. E. Wolfe).

There were three initial motivations for installing profit sharing. Some employers saw such plans in moral or religious terms; one characterized his plan as an application of "divine law" which "ushered in love, contentment, cooperation, and happiness (and) cast out hell..." (1920, U.S. Bureau of Labor Statistics). However, such employers were rare. More commonly, employers saw profit sharing as a way of building employee loyalty, thus avoiding industrial unrest and unions. Finally, profit sharing was advocated as a way of putting the employee on the side of management, thereby boosting production and efficiency (Daniel Bloomfield, 1923, p. 59).

For employers interested in building cooperative, loyal, nonunion workforces, various alternatives to profit sharing were available. Company unions and employee representation plans could be created. During World War I, the federal government fostered such "works councils," some of which persisted into the 1920's and beyond. These arrangements sometimes had "collective economy dividend" plans attached as a form of gain sharing (National Industrial Conference Board, 1922, p. 2). But employers often found that profit sharing was not sufficiently appreciated or understood by workers.

It is not surprising that profit sharing came to be unpopular with unions (1916, American Federation of Labor). Where it was used, it was often billed as an anti-union tool. Terminology was loose; employers often referred to paternalistic bonus arrangements as "profit sharing" even if they bore no relation to profits. At Ford, for example, a bonus unrelated to profits—but termed profit sharing—was distributed to workers who met company standards of morality as determined through home visits by company investigators. Union antipathy toward profit sharing was well ensconced by the late 1940's (Kenneth Thompson, 1949, pp. 43–55) and

did not appreciably shift until the recent concession bargains.

As an incentive system, profit sharing competed against a plethora of alternative arrangements. The 1920's was a period of widespread use of piece rates and other incentive plans, reflecting the earlier development of "scientific management." Roughly one-half of production workers were covered by incentive rates and bonuses. In contrast, a survey in the early 1960's found the fraction at about one-fourth (see my forthcoming article). These incentive programs were closely related to individual or group effort. But profit sharing was remote from the effort of the individual worker. Moreover, profits were affected by influences other than worker effort, so that bonuses appeared unrelated to employee achievement (Gordon Watkins, 1922, p. 517).

Thus, profit sharing had difficulty competing, either as a loyalty generator or an incentive system. It initially received unfavorable tax treatment; profit-sharing bonuses were considered non-expensable "gratuities" (Emmet, p. 6). Later, the variable compensation element of profit sharing became the antithesis of the New Deal's emphasis on income security and stability.

After World War II, unions pushed for more income stability through a "guaranteed annual wage." One union did suggest that a profit-sharing fund could be used to finance such a program (Arnold Frutkin and Donald Farwell, 1955, p. 133). But the eventual outcome was a fixed employer contribution to a supplemental unemployment benefit fund rather than a profit-related payment.

#### IV. Current Opportunities

If profit-sharing plans, or other forms of gain sharing, have desirable, external macroeconomic effects, a case can be made for subsidizing their use. At present, the tax code offers favorable treatment only to profit-sharing plans which place their bonuses into deferred (i.e., retirement) funds. Cash distributions receive no advantageous treatment. Moreover, qualified plans need not specify a fixed formula by which the bonus is determined. Thus, many profit-sharing plans

are ersatz pensions that escape the more rigorous government regulation applied to formalized pension programs.

Historically, employers who were persuaded that giving their employees a "stake" in the firm's welfare would contribute to worker loyalty, often chose various forms of employee stock ownership plans (*ESOP*) instead of profit sharing. Except in the extreme cases in which the workers own all the shares, such arrangements will not have the desirable macroeconomic effects of gain sharing. Congress, however, has been persuaded to bestow favorable tax treatment on *ESOPs*, in response to "every-worker-a-capitalist" arguments.

It is not just incentives (such as risk aversion and turnover costs) that determine firm wage policies; changes in institutions and social expectations also play a role. The wave of union wage concessions since 1979 has created an historical opportunity to promote gain sharing. Although most concessions have not involved installation of profit or other forms of gain sharing, some prominent bargains in autos, airlines, and other industries have moved in this direction. Tax incentives tailored to those forms of gain sharing which provide macroeconomic benefits—and other forms of promotion of gain sharing—could take advantage of the change in climate and promote a more stable economy.

# Profit Sharing as Macroeconomic Policy

By MARTIN L. WEITZMAN\*

When Keynes came to sum up the central message of the *General Theory* for the economics profession, in a remarkable but by now long-forgotten *QJE* article of 1937, he began with a "general, philosophical disquisition on the behavior of mankind"—under uncertainty. Here as elsewhere, Keynes made it abundantly clear that he shared Frank Knight's distinction. "Uncertainty" did not mean "risk"—that which is, at least in principle, reducible to well-defined actuarial probabilities. By uncertainty Keynes intended, I believe, to convey the idea of "ignorance"—that which is essentially due to insufficient or precarious knowledge of the mechanism by which the future is generated out of the past.

The Keynesian scenario looks out over an economic world that is rife with uncertainty. In that world, expectations play an important dual role as both a manifestation of uncertainty and a cause of it. Such expectations are arbitrary to some degree because they can be based on almost anything, including self-fulfilling expectations of the behavior and expectations of others. And, as Keynes pointed out, "being based on so flimsy a foundation," these expectations of expectations are "subject to sudden and violent changes."

It follows that while there may ultimately be some long-run forces drawing it toward full employment, capitalism may also have some deep-seated tendencies toward short-run instability. Unadulterated *laissez-faire* is likely to be out of equilibrium much of the time, and even when it is in equilibrium there is no guarantee of being in a "good" equilibrium. Whether in a state of "bad" equilibrium or merely in disequilibrium, such coordination failures generate undesirable macroeconomic consequences like unem-

ployment which can cause very significant welfare losses. By the ultimate logic of this Keynesian worldview, then, the stage is set for some form of government intervention to recoordinate the economy into a better configuration. Any such government policy will inevitably introduce some microeconomic distortions, but as an empirical matter such losses tend to be small, relative to the enormous welfare gains from having an economy operate at its full-employment level.

Such general considerations do not indicate the best *form* of government intervention to stabilize the macroeconomy. Indeed, we do not currently have a general, realistic framework within which a meta-issue like that might be properly addressed. Nevertheless it is possible, I believe, to give some common sense criteria for desirable forms of government intervention. It is my contention that economists have not been sufficiently imaginative in devising operational mechanisms or systems possessing advantageous macroeconomic properties. The usual fiscal and monetary policies are, to my mind, sledgehammer-like tactics for controlling unemployment and inflation. They do the job, but clumsily, by brute force—and they can leave a big mess afterwards. I think it is possible to find subtler alternatives that operate more cleanly and with a softer touch by taking a page from the book of Adam Smith.

A good mechanism for fighting unemployment and inflation should have several noteworthy characteristics. It should be decentralized, based on the natural microeconomic incentives of a market-like environment. It should work more or less automatically, keeping to a minimum the need for using discretionary government policy. And, in a highly uncertain world, it should be robust in retaining its desirable macroeconomic characteristics over a wide range of possible situations or circumstances—including some that are currently unforeseen.

I want to argue that a superior form of government policy for combating unemploy-

\*Department of Economics, Massachusetts Institute of Technology, Cambridge, MA 02139.

ment and inflation is to encourage, through exhortation and special tax privileges, the widespread use of profit sharing. A profit-sharing system has the potential to automatically counteract contractionary or inflationary shocks—while maintaining the advantages of decentralized decision making. And these desirable properties are robustly preserved throughout a variety of economic environments. At the very least, widespread profit sharing can be a valuable adjunct to traditional monetary and fiscal policies.

I believe we should seriously consider some new ideas about basic reform of the economic mechanism because our old ways of doing things are no longer adequate. The premier economic malady of our time is stagflation. Despite some abatement of its virulence in the immediate present, we still seem to be unable to reconcile, over a reasonably sustained period, high employment with low inflation. Even when economic conditions are on the upswing, significant pockets of unemployed workers remain throughout the Western capitalist countries. Right now, for example, we are afraid to aggressively push unemployment down to more humane levels for fear of re-igniting inflation. The policy-induced recession remains our only reliable method for lowering inflation rates. It is difficult to imagine a more costly, inefficient, or unjust waste of economic resources and human potential. Profit sharing represents a way of building into the system the kind of natural resistance to unemployment and inflation that could really disarm stagflation at its source.

Our macroeconomic problems trace back, ultimately, to the wage system of paying labor. We try to award every employed worker a predetermined piece of the income pie before it is out of the oven, before the size of the pie is even known. Our "social contract" promises workers a fixed wage independent of the health of their company, while the company chooses the employment level. That stabilizes the money income of whomever is hired, but only at the considerable cost of loading unemployment on low-seniority workers and inflation on everybody—a socially inferior risk-sharing arrangement that both diminishes and makes more

variable the real income of the working class as a whole.

Why does a profit-sharing system possess superior macroeconomic properties that help to automatically stabilize output at the full-employment level and make it easier to deal with inflation? There is not sufficient space in this condensed paper to give a detailed answer, so the true seeker must be prepared to fight through the longer and more technical pieces listed as references (1983, 1984). But a shorter heuristic story, a kind of summary, can be briefly told here.

Consider a typical monopolistically competitive firm in a partial equilibrium setting. Suppose the wage is treated as a quasi-fixed parameter in the short run. If the firm can hire as much labor as it wants, it will employ workers to the point where the marginal revenue product of labor equals the wage rate. This is familiar enough. Consider, though, what happens with a profit-sharing contract that names a base wage and a certain fraction of profits per worker to be paid to each worker. Suppose these two pay parameters are treated as quasi fixed in the short run. A little reflection reveals that if the profit-sharing firm can hire as much labor as it wants, it will employ workers to the point where the marginal revenue product of labor equals the base wage, independent of the value of the profit-sharing parameter. (Note, though, that what the worker is actually paid depends very much on the value of the profit-sharing coefficient.) When a standard *IS-LM*-type macro model is constructed around such a model of the firm, the following isomorphism emerges. A profit-sharing macroeconomy will find itself with the same output, employment, and price level as the corresponding wage economy whose wage is set at the profit-sharing economy's base-wage level. In other words, the aggregate macroeconomic characteristics of a profit-sharing economy, excepting the distribution of income, are determined (on the cost side) by its base wage alone. The profit-sharing parameter does not influence output, employment, or prices, although it does influence the distribution of income. If the employed workers can be persuaded to take more of their income in the form of profit shares and less in

the form of base wages, that can result in a Pareto improvement—with increased aggregate output and employment, lower prices, and higher real pay.

When identical-twin wage and profit-sharing economies are placed in the same stationary environment, with competitive labor markets, both economies will gravitate toward the same long-run full-employment equilibrium. But, then perform the following thought experiment. In the typical style of disequilibrium analysis, disturb each economy and observe the short-run reaction when pay parameters are quasi fixed but everything else is allowed to vary. The profit-sharing economy will remain at full employment after a disturbance, while a contractionary shock will cause a wage economy to disemploy labor. It should not be hard to imagine why such characteristics make a profit-sharing system more resistant to stagflation.

This same point can be made yet another way. Consider the standard textbook *IS-LM*-type model. Aggregate demand is determined, via the appropriate multipliers, as a function of autonomous spending injections and real money balances. The price level is determined as a degree-of-monopoly-power markup over wages. Wages are treated as exogenously fixed in the short run. Given the standard *IS-LM*-type specification, the model grinds out (as a parametric function of the wage level) output, employment, and the price level. It is clear what happens within such a model if there is a *ceteris paribus* money-wage cut. Output and employment are higher, while prices are lower. Yet this is exactly what occurs when an economy shifts toward profit sharing. The base wage determines the fundamental macroeconomic characteristics of the system—when there is an increase in profit shares at the expense of base wages, macroeconomic performance improves without loss of real labor income.

I am aware that such short-run, fixed-pay-parameter, disequilibrium models will be unsatisfying to the economic theory purist who will want a full-blown account of why one payment mechanism rather than another has been selected by society in the first place, and who will not rest content without under-

standing on a more fundamental level why pay parameters should be sticky in the short run. Such concerns have a legitimate place. But I do not think they should be taken to such an extreme that we are inhibited from examining what would happen in disequilibrium under alternative payment systems before first having firmly in hand a general, all-encompassing theory of economic systems and disequilibrium-like behavior.

What about the possible objections to profit sharing? Several are frequently voiced. I believe the objections can be successfully rebutted, but here I deal with only one, and that skimpily. The objection to profit sharing one hears most often from economists is that, compared with a wage system, it represents a socially inefficient method of risk sharing. (Isn't it obvious that under a wage system, the firm bears the risk, while under a profit-sharing system, the worker bears the risk?) In my opinion the reasoning traditionally put forward to support this "insurance" argument is fallacious, being based on a partial equilibrium view that does not take into account the radically different macroeconomic consequences of the two systems for overall employment and aggregate output. The fixed wage does not stabilize labor income. What is true for the individual tenured worker is not true for labor as a whole. When a more complete analysis is performed, which considers the situation not as seen by a tenured, high-seniority worker who already has job security, but by a neutral observer with a reasonably specified social welfare function defined over the entire population, it becomes clear that the welfare advantages of a profit-sharing system (that delivers permanent full employment) are enormously greater than a wage system (that permits unemployment). The basic reason is not difficult to understand. A wage system allows huge first-order Okun-gap losses of output and welfare to open up when a significant slice of the national income pie evaporates. A profit-sharing system stabilizes aggregate output at the full-employment level, creating the biggest possible national income pie, while permitting only small second-order Harberger-triangle losses to arise because some crumbs have been randomly

redistributed from a worker in one firm to a worker in another. Here is a friendly challenge to would-be critics. I challenge anyone to cook up an empirical real world scenario, with reasonable numbers and specifications, where a profit-sharing system does not deliver significantly greater social welfare than a wage system.

The superior profit-sharing variant of capitalism is practiced, to some extent, in the immensely successful economies of Japan, Korea, and Taiwan. While these countries are not identical clones, their economies do share certain important characteristics. In each case workers receive a significant fraction of their pay in the form of a bonus. The bonuses are large, averaging over good years and bad about 25 percent of a worker's total pay in Japan, and about 15 percent in Korea and Taiwan. The degree to which the bonus is actually determined as a function of current profits per worker varies from firm to firm, and depends upon the country. (For example, in some Japanese companies the bonus is almost a disguised wage, but this is not true for most Japanese companies, and it appears to be hardly true for any Korean companies.) Bonuses, like dividends, respond to corporate earnings, but with a complicated lag structure not easy to quantify by any rigidly prescribed rule. Overall, there is very little question that profit sharing is a significant feature of the industrial landscapes of these "Japanese-style" economies.

While it is difficult to quantify the exact magnitude of its contribution out of a host of reinforcing tendencies, the bonus system is almost surely one major reason (although, most likely, far from the only reason) for the outstanding economic performances of Japan, Korea, and Taiwan. Their flexible payment system helps these economies to ride out the business cycle with relatively high, stable levels of employment and output. Their governments enjoy greater leeway for fighting inflation without causing unemployment. The variability of real pay per member of the potential labor force has actually been reduced. Over time, a more equitable distribution of income has emerged than is found in other capitalist countries.

I believe that we in the West, instead of giving lessons as we are accustomed to doing, now must be prepared to take a lesson from the East. We should consciously tilt our economies toward this superior variant of capitalism. We ought to adopt a new social contract that promises our working people full employment without inflation but asks, in return, that workers receive a significant fraction of their pay in the form of a profit-sharing bonus.

But, the typical economist will ask, why if a profit-sharing system represents a far better way of operating a market economy than a wage system don't we see more examples of share economies? After all, even in Japan, Korea, and Taiwan only modest (although significant) steps have been taken in this direction. The rest of the advanced capitalist countries are predominantly wage economies. Why, if profit sharing is so beneficial, does not self-interest automatically lead firms and workers in this direction?

The answer involves an externality or market failure of enormous magnitude. In choosing a particular contract form, the firm and its workers only calculate the effects on themselves. They take no account whatsoever of the possible effects on the rest of the economy. When a firm and its workers select a labor contract with a strong profit-sharing component, they are contributing to an atmosphere of full employment and brisk aggregate demand without inflation because the firm is then more willing to hire new "outsider" workers and to expand output by riding down its demand curve, lowering its price. But these macroeconomic advantages to the outsiders do not properly accrue to those insiders who make the decision. Like clean air, the benefits are spread throughout the community. The wage firm and its workers do not have the proper incentives to cease polluting the macroeconomic environment by converting to a share contract. The essence of the public good aspect of the problem is that, in choosing between contract forms, the firm and its workers do not take into account the employment effects on the labor market as a whole and the consequent spending implications for aggregate

demand. The macroeconomic externality of a tight labor market is helped by a share contract and hurt by a wage contract, but the difference is uncompensated. In such situations there can be no presumption that the economy is optimally organized and society-wide reform may be needed to nudge firms and workers towards increased profit sharing.

This much-needed reform will not come about easily. Persuading workers and companies to change fundamentally the way labor is paid, in the name of the public interest, will demand political leadership of a very high order. Material incentives will probably be required, such as favorable tax treatment of the profit-sharing component of a worker's pay. Yet the benefits of full employment

without inflation are so enormous and the increased income is so great, that we cannot afford not to move in this direction.

# THE CONSEQUENCES OF DEREGULATION IN THE TRANSPORTATION AND TELECOMMUNICATIONS SECTOR†

## The Regulatory Transition

By JOHN R. MEYER AND WILLIAM B. TYE\*

A number of regulated industries, particularly in transportation and communications, have recently undertaken the transition from a regime of rigid price and entry controls to that of a more competitive market structure. While the different industries have experienced somewhat different fates, the responses to this transition do have certain common underlying characteristics.

To start, demands for some form of temporary or continuing regulation during the transition to deregulation can be explained almost entirely as a response to the strength of the entry threat relative to the magnitude of sunk costs incurred by the affected parties in the previous regulatory regime. Where the obstacles to entry are low, the incumbent firms and labor ordinarily seek "protective conditions" during the transition to permit them to recover some or all of their sunk costs. When the obstacles to entry are high, customers are likely to make similar demands for protective conditions designed to do the same, particularly when the customers' own sunk costs severely restrict their competitive options after deregulation.

Pleas for protective conditions during the transition are widely regarded as introducing market imperfections that should be resisted in the name of regulatory reform. This view, however, naively equates the market results during the transition (when choices are constrained by the presence of sunk costs) to the results that would prevail in a long-run equilibrium where deregulated prices and quanti-

ties are established in the absence of most (or any) sunk costs. The regulatory problem during the transition is to define a set of residual (hopefully self-terminating) economic constraints that will satisfy the equity and other considerations created by the short- to medium-term continuation of some sunk costs without creating insurmountable obstacles to approaching an efficient competitive outcome in the long run.

Any transition mechanism must thus come to grips with the essence of the transition problem from a political as well as an economic perspective: who is to bear the consequences of the "overhang" of sunk costs. Note that we are not making a generalized plea for the compensation of losers from deregulation, especially for windfall gains conferred by the regulatory process itself (see Kenneth Gordon, 1981). Rather, the transition problem is defined here to be a limited period in which participants in the regulatory game are permitted to amortize financial commitments made under the prior set of rules while other participants are constrained in their ability to exploit the presence of those sunk costs during the transition. Misunderstanding or failing to recognize this transition problem can pose substantial dangers: specifically, premature application of economic concepts that, while arguably valid in some future regime in which all sunk costs are amortized, decidedly do not account for the effect of these sunk costs on the marketplace in the short run. Misunderstandings of the transition problem may also encourage false conclusions about the eventual results of deregulation, that is, the long-run competitive equilibrium and industry structure that will emerge. As a consequence, policy recommendations designed to address the problems of the transition may

†*Discussants:* Robert Willig, Princeton University; Thomas Moore, Hoover Institution.

inadvertently frustrate the ultimate goal of deregulation.

The transition problem arising from sunk costs is exacerbated by the fact that deregulation also undermines the prior "regulatory equilibrium." That equilibrium, even though it might bear little resemblance to a true market equilibrium, usually did manage to apportion the total costs of the regulated enterprise in a fashion that more or less kept the factors of production committed. Typically, regulators instituted what amounted to informal taxation schemes. Under these schemes, different consumers, sometimes aided by government subsidies, paid the needed revenues but individual charges often bore little resemblance to the individual costs of the services performed, so that "contributions" could vary widely from one activity to another. Finding a "revenue-adequate" substitute for the old regulatory excise tax scheme during the transition to deregulation can be a difficult task, giving rise to numerous tradeoffs and conflicts, especially if combined with efforts to protect certain so-called captive or otherwise highly dependent classes of customers.

All these problems of defining revenue adequacy and achieving it without unleashing too many political charges of unfairness are perhaps best illustrated by the railroad industry, now into its fifth year of regulatory reform under the *Staggers Rail Act*. According to the *Staggers Act*, implementation of national transportation policy should start with the presumption that 1) an effectively competitive sphere and a (largely transitory) "market-dominant" sphere coexist in the rail industry; 2) regulation over rate reasonableness is to be maintained only in markets where there is an absence of effective competition; and 3) competition should be nurtured and encouraged in order to maximize the size of the competitive sphere and thus minimize the need for residual economic regulation in the market-dominant sphere. Thus, in the *Staggers Act*, Congress established a so-called reasonable "base rate" (which could be escalated for inflation and revenue-adequacy needs) for captive shippers where the Interstate Commerce Commission (ICC) found the presence of market dominance. All

other existing rates (competitive shippers) were essentially deregulated insofar as rate reasonableness was concerned. In essence, Congress was responding to shippers who feared that they would be charged "unreasonable rates" during the regulatory transition because they had sunk substantial costs which made them captive to a single carrier, for example, a coal-fired electric generating plant with a remaining lifetime extending over several decades consuming coal purchased under long-term contract from a specific mine served by only one railroad and with no viable barge or other transport alternatives.

After the passage of the *Staggers Act*, numerous economists (William Baumol, Robert Willig, and Stephen Goldfeld, 1981; and Mark Levin and Bruce Stram, 1981) endorsed Ramsey Pricing<sup>1</sup> as the economically rational standard for setting rail rates in the captive sector. Many shippers, though, wondered how a rate design predicated on assigning the highest rates to captive shippers (indeed, whatever it took for the railroad to become revenue-adequate, subject only to the shippers' unaided search for alternatives) qualified as what Congress had in mind as a transition device to protect captive shippers under the *Staggers Act*. Apparently in response to this criticism, the ICC moved to constrain the results of Ramsey Pricing with a so-called "surrogate for competition," the Stand-Alone Cost (SAC) test (ICC, 1983) which "...in brief, requires that the consumer of a service be charged a price no higher than that at which it could be offered by a *specialized* competitive supplier" (Baumol and Willig, 1983, p. 7; emphasis added).

Critics of Ramsey Pricing and the SAC test have argued that these concepts are not

<sup>1</sup> Ramsey Pricing, a variant of value-of-service pricing or the Inverse Elasticity Rule, sets the highest rates for the most demand-inelastic traffic (E. P. A. Ramsey, 1927; Harold Hotelling, 1938; Baumol et al., 1962; and Baumol-David Bradford, 1970). In the context of railroad ratemaking, Ramsey Pricing (and its economic rationale) was largely anticipated in the concept of value of service ratemaking and the writings of D. Phillip Locklin (1933).

responsive to Congressional intentions to protect captive shippers (see Tye, 1983a,b) nor are they practical to implement (Tye and Herman Leonard, 1983; and Tye, 1985). In particular, they object that the SAC test is a very poor surrogate for real competition. A true "surrogate," they argue, must look to *all* the constraints on market power in a competitive market—intramodal, intermodal, product, and geographic. The *specialized* SAC test is a poor surrogate for the richness of this competitive environment because it only looks at a very narrow kind of potential competition, that of a specialized entrant who by definition could never flourish in the purported environment, that of strong economies of scope. Such economies arise if the total costs to a carrier of supplying multiple services simultaneously is less than the sum of the costs of supplying each of them separately. (See Willig, 1983; and John Panzar-Willig, 1977.) Joint costs are one origin of economies of scope (see Panzar-Willig, 1981). These critics therefore view the SAC test as a necessary but hardly sufficient surrogate for effective competition and not the only reliable measure of a maximum reasonable rate during the transition.

Proponents of Ramsey Pricing and the SAC test never explicitly define their vision of the equilibrium industry structure after the transition, but it can be inferred from their assumptions (implicit and explicit) about cost structure and their policy prescriptions for the transition. Their vision seems to be a rail industry with allegedly marked economies of scope and scale where average prices must be substantially above long-run marginal cost in order to achieve revenue adequacy (Tye, 1984). With such a vision of the deregulated equilibrium, Ramsey Pricing (reined in only by the SAC test) during the transition could well become mainly a redistributive device, transferring much of the burden of unwinding unneeded investments in rail capacity onto certain captive shippers, as contrasted, say, with placing that burden strictly on rail labor and capital. This obviously raises equity issues that seem better suited to political than economic adjudication.

Furthermore, discriminatory prices that cannot be sustained in the long run because

of broader (nonintramodal) competition may be self-defeating for the railroads (and therefore presumably avoided by management with perfect foresight and complete control). Specifically, if a railroad is economically viable in the long run, it is not in the railroad's self-interest to undermine or relocate a shipper—especially a captive shipper—as long as that shipper pays rates that make a positive contribution to covering nonallocable costs. Even if the railroad contemplates going out of business (for example, abandoning service to a particular shipper), an optimal rate policy would take into account possible tradeoffs between maximizing current contribution and the rate at which the shipper went out of business; that is, a lower rate today might yield a larger discounted net value of contributions. Another, somewhat opposite danger for carriers practicing price discrimination is that they may further sink costs during the regulatory transition (based on the mistaken belief that highly discriminatory pricing structures are a permanent feature of a competitive market), only to discover that their captive shippers have slipped from their grasp, once again leaving them revenue-inadequate.<sup>2</sup>

Lower rates in markets temporarily glutted by overcapacity may also not be an unmitigated benefit to the shipper or consumer, especially if the transient character of the low rates is not understood. Again, if the low rates are mistakenly expected to persist, "downstream" investments or locations may be incorrectly chosen by shippers. Indeed, this is essentially the "mistake" made by many of today's captive shippers in that they incorrectly thought that regulation would perpetuate the historical rate patterns. Of course, the converse could also occur: excep-

<sup>2</sup>Proposals to pursue more short-run or discriminatory pricing schemes in the rail industry have been strongly endorsed by practitioners of the theory of "contestable markets," with its strong emphasis on the role of sellers' sunk costs. This endorsement is paradoxical, given that Ramsey Pricing implies overlooking buyers' sunk costs for pricing policy during the regulatory transition. Such a system of essentially unfettered price discrimination can be enforced only with the constraints on buyers' choices that such sunk costs temporarily provide.

tionally high rates assessed on today's captive shipper might deter investments or reinvestments that might be mutually beneficial to both the investor and the carrier in the longer run. In short, substantial departures from prices based on long-run cost considerations, even though sometimes bestowing short-run benefits, have a good deal of potential for achieving misallocation of resources and other economic mischief in the long run. This is especially likely to be true in an economy characterized by rapid technological and demographic changes that are constantly opening up new economic possibilities and combinations.<sup>3</sup>

Problems of matching financial commitments and risks, or of becoming captive to a single vendor, are, of course, not unique to the rail industry. They often arise when a long-lived investment is to be used by multiple tenants. Once committed to such a project, joint costs are substantially sunk and the tenants have closed off other options. For that reason, there is no true market solution for allocating the joint costs among captive users once they are sunk. However, a market for long-term contracts could have accomplished these objectives in the absence of regulation. Given the risks of committing to large amounts of fixed capacity for long periods of time (for example, in bulk shipping, power plants, commercial office space, mining operations, oil pipelines, air terminals, etc.), investors usually size their installations to match long-term contractual commitments made by buyers, though sometimes reserving some extra capacity for the "spot" market or growth in demand (Meyer, 1983). Such contracts shift some of the risk to buyers who are presumably more knowledgeable about their future demands than sellers, and insulate sellers from the rate wars which inevitably break out on the spot markets when excess capacity persists over sufficiently long periods. Equally as important, such contracts permit customers to make decisions that leave them "captive" to suppliers; that is, they are then free to make

decisions to sink additional costs that substantially reduce their access to competing vendors.

Had the rail industry developed without regulatory oversight, such a "contracting equilibrium" might already be in place. Unfortunately, recreating that equilibrium retroactively is not easily done—for otherwise it would seem to be a good approximation to the *ex post* "surrogate for competition" that Congress and the regulatory commissions seek. Among other problems is how to treat *ex post* "excess capacity"; in concept, both shippers and carriers agree that shippers should pay only the cost of "needed" capacity, but that concept immediately invokes debate over how much capacity would be provided in a "freely contracted" competitive equilibrium. In general, much of the extant capacity in the industry might never have been constructed (or maintained) without prior contractual commitments from some shippers to pay substantially more than they can be assessed under an *ex post* deregulated scenario. A conflict once again arises between the *Staggers Act* objective of revenue adequacy, which would suggest making the captive shipper bear these sunk costs in the short run, and the *Staggers Act* guarantees to captive shippers, which suggests that the carrier bear them if competition precludes recovery from the competitive sector.

In a "contractual approach" to the regulatory transition the existence of barriers to entry and substantial sunk costs would also mean that prices would never be set by "hit-and-run" entry, as in more competitive or contestable markets. Above all, the contractual approach directs attention to the long-run choices made when buyers have few or no sunk costs, including all the competitive choices available in the long run—intermodal, intramodal, product, and geographic. Price discrimination arising from buyers' and sellers' sunk costs should not exist in such a "contractual equilibrium."

The resulting rate ceiling for captive shippers during the transition could, of course, be substantially less permissive than that offered by the SAC test. Such a policy, though, should have a better chance of maintaining the consensus for deregulation during the transition and would also represent a

<sup>3</sup>The rail industry has not been noted for its ability to foresee long-term trends and to change its pricing strategy in response (see Meyer et al., 1959).

clear signal to the carriers that the transition to a deregulated environment will be swift and that they will not be afforded the luxury of a slow adjustment at the expense of the captive shipper. In general, any deregulated industry should not be encouraged to use residual regulation during the transition process to seek additional ways to preclude efficient choices by shippers, choices they might accept freely under contract. Such a policy will only encourage those customers to seek out alternatives that do not use these recently deregulated services while perhaps tempting carriers and regulators to seek new ways of restricting competition in an effort to extend the transition period.

In short, two distinctly different regulatory transitions can be identified which raise different equity and welfare problems and require somewhat different policy responses. One situation is characterized by relatively easy entry and few commitments that tie particular consumers to particular vendors. The other is characterized by limited entry possibilities and some consumers who have sunk costs or made commitments that do tie them for at least some time to particular vendors. Of course, in the real world the two situations will rarely be encountered in pure forms but rather in mixes, so that mixed-policy strategies may also be advisable.

In the first situation, that of relatively free entry, economists' notions of workable competition or contestable markets, however labelled, will seem largely applicable and little or no residual regulation will be needed to protect consumer interests. Indeed, complaints about deregulation in such circumstances are more likely to originate with the factors of production—labor and capital—for whom deregulation can often mean erosion of a previously privileged position (i.e., capture of rents created by the regulatory process itself). But from the standpoint of consumer (or shipper) interests alone, a prompt, almost immediate, transition would seem advisable (Alfred Kahn, 1979).

By contrast, in the second situation the transition process can involve some aggrieved consumers who perceive themselves as unfairly victimized by the transition. The difficulty is created by an overhang of sunk

costs committed under the prior rules of regulation. Eventually, these problems will be resolved by the means usually employed in a market economy when long-term commitments must be made by different participants in an enterprise—the establishment of mutually satisfactory contractual agreements between the participants. Until then, however, public policy is likely to be confronted with some difficult decisions of equity, in which the different participants can make plausible claims about the justice or injustice of different policies. Designing an acceptable regulatory transition in these circumstances will almost certainly be difficult and time consuming.

Are there any economic guidelines for steering public policy through these transition difficulties and compromises? Above all, appropriate public policy during the transition should avoid trying to outguess the market by imposing regulatory actions designed to achieve preconceived visions of the long-run industry equilibrium. (In a world of rapid technological, demographic, and other changes, forecasting the eventual equilibrium is likely to be beyond anybody's vision, including that of the most enlightened regulator.) The danger of these regulatory interferences is greatest where these actions foreclose competitive options during the transition. Another suggestion, actually embodied in the *Staggers Act*, is to move away from the prior regulated structure only slowly, and then in a rigidly specified fashion, wherever substantial segments of captive consumers continue to exist. Still another thought is to keep particular rates as much in line as possible with the underlying long-run marginal costs of supplying a particular activity, despite the possible short-run welfare advantages of certain price discrimination schemes. It should never be forgotten that in a market economy, whenever prices for any activity rise disproportionately above the underlying cost fundamentals, business ingenuity (in the form of new or altered technologies, product and location substitutions, etc.) is quickly applied to finding ways to do with less. In many ways, this is the fundamental lesson of the long and tortured history of ICC regulation of the railroads, to a lesser

extent of FCC regulations of long-lines telecommunications, and most recently of the OPEC cartel's efforts to set international oil prices. To paraphrase Keynes—in the long run not only are we all dead but with provision of enough incentives, all demands are elastic.

# "Let Them Make Toll Calls": A State Regulator's Lament

By ROGER G. NOLL\*

In the late 1960's, the Federal Communications Commission (FCC) introduced competition into telecommunications. Initially limited to specific services and types of customer equipment, the limits soon gave way. By 1980, the FCC's policy was to promote competition.

In 1982, the Antitrust Division settled its suit against AT&T with close to total victory, achieving divestiture of the Bell Operating Companies (BOC). AT&T remains in equipment and interexchange services, which are growing increasingly competitive. To facilitate divestiture, the FCC adopted several policies: asserting jurisdiction regarding depreciation and then adopting methods that more nearly reflect economic costs, eliminating regulation of equipment prices, and restructuring the procedures whereby interstate services share local exchange costs.

Two aspects of these new policies are worth emphasizing. First, astonishingly enough, economics played a central role in changing federal telecommunications policy, as acknowledged by Philip Verveer (1984), the lawyer who developed the antitrust case against AT&T, the Chief of the FCC's Cable Television Bureau when cable was deregulated, and the Chief of the Common Carrier Bureau when the FCC formally adopted the policy of minimizing federal regulation of telecommunications. The intellectual foundation of these policies is an economic case that the industry will be more efficient if it is minimally regulated and maximally competitive.

Second, the new federal policy is widely despised by state regulators. My title is from an eloquent decision in Texas, which also characterized cost-causative pricing as from the "Marie Antoinette School of Rate Design" (Mary Ross McDonald and Angela

Marie Demerle, 1984, p. 35). State regulators dislike federal procompetitive policy because it transferred several billion dollars of revenue responsibility to the states and threatens state regulatory policies. Thus far, the state response has hardly been accommodative. Instead, federal and state regulators are fighting a three-front "Jurisdiction War." This paper briefly analyzes the economics and politics of state resistance to federal policies. For more details, see my companion paper (1985).

## I. The Economics of State Telecommunications Regulation

The source of the conflict lies in the methods that states use to regulate telecommunications. The most important features of state ratemaking are allowable cost estimation, interjurisdictional revenue sharing, rate averaging, and residual pricing.

*Allowable Cost Estimation.* Regulators are supposed to assure that regulated service is provided at reasonable cost and that a regulated utility recovers useful investments and earns reasonable profits. Regulation is not public enterprise; firms have considerable latitude in making normal business decisions. Commissions normally ascertain whether investments are needed, and sometimes determine whether the prices paid by utilities are reasonable, but they rarely question decisions regarding network design or the technical characteristics of services. Once the investment is approved, its costs and profit enter permanently into the firm's revenue requirement.

The key consequences of allowable cost practice are that it is unlikely to force a utility to minimize the cost of service, and that investment risks are not borne by the utility. Hence, the allowed cost of an investment need bear no relation to its economic value. Should unanticipated changes in technology or market structure render an asset

\*Stanford University, Stanford, CA 94305.

uneconomic, it nonetheless remains in the rate base, and regulators are obligated to find sources of revenue for it.

Divestiture and federal deregulation apparently have left local telephone companies with substantial uneconomic, incompletely amortized assets. Virtually all equipment owned by BOCs was manufactured by Western Electric. Judging from postdivestiture events, Western apparently was a high-cost supplier of several important lines of equipment. Since divestiture, Western has lost market share, closed manufacturing facilities, and engaged in cost-reducing actions to compete for business. If the BOCs paid super-competitive prices for equipment, their books overstate the economic value of their assets. Accounting practices in telecommunications also work to overstate asset values. Examples are excessively slow rates of depreciation and capitalization of some recurring expenses (for details, see Nina Cornell and myself, 1985).

The problem for state regulators is that competition severely constrains, if not undermines, the prospects of paying for uneconomic assets. As the FCC deregulates interstate toll, customer equipment, cable television, domestic satellites, and several technical challenges to the local exchange system, the state's ability to maintain regulated intrastate prices above economic cost diminishes.

*Interjurisdictional Revenue Sharing.* Most interstate telecommunications service connects to the interstate network through the local exchange. Regulators have developed formulas whereby interstate services pay for this use. The procedure divides local exchange costs into those that vary with use and those that are nontraffic sensitive (*NTS*). The former are allocated among jurisdictions on the basis of relative minutes of use (for example, fully allocated costs). In the past, the latter were allocated according to an economically meaningless formula which caused interstate service to pay about 25 percent of local *NTS* costs with this fraction growing rapidly. The formula was negotiated among the FCC, state regulators, and the industry, but the FCC unilaterally terminated it, capped the federal contribution at 25 percent, and changed the method of raising the

interstate *NTS* contribution. The FCC had imposed an excise tax on interstate toll, based on minutes of use. In 1984, the FCC adopted an "access charge"—a fixed monthly payment for access to long distance through the local *NTS* plant.

Historically, states have regulated the monthly rate for local service. The FCC's access charge adds between \$2 and \$6 to this rate. Economically, although the issue is complicated (see Robert Willig, 1979), a hookup charge is a sensible way to cover *NTS* costs; politically, state regulators see it as transferring federal *NTS* charges to the states. Regulators believe that customers are unlikely to grasp the subtle distinction between the federal and state components of basic rates. Functionally, the FCC's decision uses the monthly flat rate to cover the costs of uneconomic assets. Thus, as competition made covering the state share of these costs more difficult, the FCC preempted one possible escape by raising the flat monthly rate.

*Rate Averaging.* Common regulatory practice sets the same price for any given service for all customers. Consequently, basic service rates do not reflect differences in the cost of service.

Although *NTS* costs vary for many reasons, the most important cause is population density. Most *NTS* costs are copper wires connecting a customer to the first switch in the network. In sparsely populated areas, connection distances can be several times as great as in urban areas. Thus, rate averaging creates a massive subsidy of rural service. The average federal contribution to *NTS* costs for business and residential users is about \$6 per month, but in rural states it is much greater, reaching \$25 per month in Wyoming (Congressional Budget Office, 1984).

Some investment in rural service probably is uneconomic. Rural residents may be unwilling to pay for telephone service that is priced at its accounting cost. Moreover, copper-wire technology probably is not the cheapest way to serve rural areas. Instead, recent technical advances probably make over-the-air technologies, such as cellular radio, cheaper in some areas than the book value of a rural *NTS* plant. If so, the eco-

nomic value of an existing plant falls short of its book value.

The regulator's problem is to find revenue to pay for expensive rural service. The FCC's access charge places a greater burden of cross subsidization on the monthly flat rate, with nontrivial distributional consequences across categories of users. Moreover, it underscores the interstate subsidy flow. State regulators in the urbanized Northeast believe that residences and small businesses in their jurisdiction will pay a larger, more visible subsidy to western ranchers.

*Residual Pricing.* The plight of the states is largely of their own doing, resulting from traditional ratemaking philosophy: residual pricing. Economics, efficiency, and cost causation play a tiny role in intrastate rate-making. Instead, pricing begins by designating "basic" services as having special social importance. The installation charge and the monthly flat rate for local service are accorded such status everywhere, and in some states so is the price of local pay calls. Within the limits of economic feasibility (for example, demand elasticities) and "fairness," an increase in revenue requirements is covered by price increases for nonbasic services. The remaining revenue requirement—the residual—is covered by price increases in basic services.

Because residual pricing considers only total costs, the prices of nonbasic services are set roughly to maximize gross revenues, subject to a loose political constraint on the acceptable magnitude of a price increase. This implies demand elasticities for nonbasic services at or near unity, and much lower demand elasticities for basic service. Residual pricing also permits pricing some nonbasic services below economic costs. Because services do not face a meaningful cost test, the price that maximizes gross revenue need not be higher than average or marginal cost. Again, although data are fragmentary, evidently some intrastate services, notably private lines and Centrex, are so priced.

The argument supporting residual pricing has been the "universal service" objective, where this means maximizing the number of subscribers to telephone service. State regulators fear that cost-causative prices for basic

service would cause significant disconnections from the telephone network. This fear is not justified. Briefly, estimates of the demand elasticity for basic service are very low, and prices based on economic costs probably would not differ much from current prices, except in rural areas.

Residual pricing worsens the problems facing state regulators. As they seek to cover revenue requirements, they begin with prices for most services that roughly maximize gross revenues. Moreover, competition threatens to make firm-specific demand curves more elastic. Only the politically most visible service has a small demand elasticity, and here, the FCC has preempted the first big price increase.

## II. Jurisdiction Wars

Policy conflicts between state and federal regulators take many forms: equity vs. efficiency, regulation vs. competition, residual pricing vs. cost-causative pricing, etc. Underlying these is the deeper problem of paying for undepreciated uneconomic assets and expensive rural service when technological change and competition are increasingly likely to attack overpriced services.

The process by which these conflicts are revealed and resolved is a jurisdiction war. The condition necessary for a jurisdiction war is that two regulatory authorities have conflicting policies, and sufficiently overlapping responsibilities that decisions by one substantially affect the ability of the other to achieve its objectives.

For example, the FCC seeks a competitive interexchange toll industry. The companies providing interstate service can use their facilities to compete for local toll. If states handicap local competition to retain a source of revenues for local exchange companies, they inhibit FCC policy and raise the cost of toll in the FCC's jurisdiction.

The FCC also promotes competition in customer equipment. One example is the PBX, a switch on a customer's premises that connects office extensions. Customer PBX competes with Centrex, a service offered by local exchange companies that uses the local network for interextension calls. If state reg-

ulators underprice Centrex, they destroy PBX competition; however, if state regulators price Centrex above costs, PBX sales erode its market. This situation illustrates the efficiency benefits of competition, but also demonstrates how decisions by one jurisdiction affect the other, and hence create inter-jurisdictional conflict.

Jurisdiction wars are fought on three fronts. First, one agency adopts regulations that undermine the other's policies. For example, low federal prices for interstate private line service constrain intrastate toll prices. States cannot prevent the use of interstate private lines and return interstate toll to reach an intrastate destination.

Second, one agency asserts jurisdiction over another or in an unregulated area. Examples are depreciation, where the FCC took responsibility away from the states, and cellular radio, where the FCC used its authority to allocate the electromagnetic spectrum to introduce two-firm rivalry, whereas states would prefer to make cellular radio part of the local telephone monopoly.

Third, one agency attacks another through political overseers, especially legislators. In 1984, after the access charge decision, state regulators lobbied Congress for relief. Congress convinced the FCC to delay its decision for residential users until early 1985. Previously, state regulators unsuccessfully sought legislation to limit deregulation and to undermine the antitrust cases against AT&T.

For economic, technical and political reasons, the states appear destined to lose the jurisdiction war on all three fronts. In interactive regulations, the FCC has economics and technology on its side. Competition and, where there is regulation, cost-causative pricing will undermine state policies wherever the two overlap, for the former will cause local exchange companies to retain subsidized activities while losing subsidizing business. Moreover, by regulating the electromagnetic spectrum and cable television, the FCC controls the technologies that most threaten the local telephone network.

The FCC also holds the cards in direct battles over jurisdiction. The courts permit the FCC to assert jurisdiction wherever it can show a connection between its statutory

policy responsibilities and the domain it seeks to regulate. The FCC acquired jurisdiction over cable television because cable affected the regulation of broadcasting, and over depreciation of the local exchange because it affected interstate pricing. Most likely, the FCC could assert jurisdiction over all of telecommunications, for the interconnectedness of the network makes impossible a clean, noninteractive jurisdictional separation.

On the political front, the states have the best hope for success. Mayors and state office holders are the potential competition for incumbents in congress. If local telephone rates become politically salient, the no-risk strategy for Congress is to preempt the issue by restoring the status quo ante.

Two factors make this unlikely. First, rate increases are unlikely to be large enough to become one of the few issues that are salient in legislative elections. Second, the politics of telephone pricing is likely to turn against most state regulators as data reveal that most of the problem is traceable to a rural subsidy.

Starting with *Baker v. Carr* in 1962, the Supreme Court issued several decisions clarifying the constitutional requirements for legislative districts at all levels of government. The enunciated policy, "one man, one vote" in that gender insensitive era, massively rearranged legislative districts and vastly reduced the legislative influence of rural areas (see Mathew McCubbins and Thomas Schwartz, 1984). It also caused reductions in rural subsidies, or a transformation of them to programs with a broader base (for example, food stamps).

The institutionalization of pricing policies that subsidize rural telephone service took place before redistricting. Moreover, rapidly advancing technology caused real telephone prices to fall throughout the 1970's, thereby attracting no political attention. Following Paul Joskow's (1974) observations about the asymmetry of political responses to increases vs. decreases in regulated prices, new federal policy focuses political attention on the intrastate prices that will increase. In the information-poor world of telecommunications regulation where the incidence of costs and subsidy burdens is obscure, the initial politi-

cal response is to view these increases with alarm. As political leaders receive information that the issue is yet another rural subsidy, the politics should change. This does not imply that rural subsidies will end, but that political pressure will emerge to develop a more targeted, smaller rural subsidy, perhaps with help from legislative appropriations.

The final interesting question is whether state regulators will move quietly toward less regulation and more efficient prices, or will go down fighting. The longer state regulators delay, the more costly will be the change when it comes because with competition, cross subsidization will cause inefficient patterns of investment by entrants and customers. Politics is normally reactive, so rational state policy probably requires that regulators be in front of political leaders, and take early actions that displease them. Such bureaucratic entrepreneurship has a precedent, for it was practiced by several federal regulatory agencies during the 1970's, including the FCC.

# Intercity Transportation Route Structures under Deregulation: Some Assessments Motivated by the Airline Experience

By STEVEN A. MORRISON AND CLIFFORD WINSTON\*

During the past decade, the United States intercity transportation system has undergone significant changes owing to legislation that effectively deregulated the major transportation industries. This paper assesses the effects of transportation deregulation on carriers' route structures, using as motivation experience from airline deregulation. Route structure changes have important implications for the level of service that many travelers and shippers will receive in the new transportation environment. We first summarize the major results from our (1984) study on the welfare effects of airline deregulation. The implications of these findings are then used as a basis for analyzing the route structures of the major modes in the deregulated environment.

## I. Welfare Effects of Airline Deregulation

Our earlier paper was concerned primarily with analyzing the welfare effects on passengers of airline deregulation. We assembled a sample of passenger trips over roughly 800 different routes, encompassing every level of passenger flow density based on hub classification.<sup>1</sup> Utilizing this data base, we calcu-

lated the change in business and pleasure travelers' welfare (i.e., compensating variations) that resulted from fare, entry, and exit deregulation. Our major finding is that, in 1977 dollars, the welfare increase for all travelers is \$5.7 billion. Decomposing this net welfare change, we find the average welfare change per passenger trip due to fare changes is \$4.04, to travel time changes is -\$0.96, and to frequency changes is \$8.00.

Although our finding of a substantial welfare gain from deregulation is consistent with economists' policy recommendations and predictions (see Winston, 1985), the explanation that underlies it is not. Conventional wisdom (pioneered by George Douglas and James Miller, 1974) held that regulation led to excessive fares accompanied by superior service quality, particularly departure frequency, compared to what would be generated in a deregulated environment. Deregulation was therefore believed to be socially beneficial because it would lead to fare reductions that would more than compensate for reductions in service quality. We found, however, that the largest source of the welfare gain from deregulation occurred (on average) through increases in departure frequencies.<sup>2</sup>

A summary of our data, presented in Table 1, shows the improvements in departure frequencies that resulted from deregulation. These percentage changes, which include direct and connecting flights, correspond to a route-weighted average increase in frequen-

\*Department of Economics, Northeastern University, Boston, MA 02115, and Economic Studies Program, The Brookings Institution, 1775 Massachusetts Avenue, NW, Washington, D.C. 20036, respectively. We are grateful to Joan Winston for significant contributions to this research.

<sup>1</sup>An individual community falls into one of four hub classifications based on that community's percentage of total enplaned revenue passengers at U.S. airports. Those communities enplaning 1 percent or more of the total are classified as large hubs, communities enplaning between .25 and .99 percent of the total are classified as medium hubs, communities enplaning between .05 and .24 percent of the total are classified as small hubs, and communities enplaning less than .05 percent of the total are classified as nonhubs. In 1977, there were 25 large hubs, 39 medium hubs, 94 small hubs, and 471 nonhubs.

<sup>2</sup> This finding assumes that pleasure travelers paid the median discount fare under both regulation and deregulation, and that all business travelers paid the coach fare under regulation, but one-half paid the coach fare and one-half paid the median discount fare under deregulation. The assumed proportions of discount fare travel are consistent with Air Transport Association *Monthly Discount Reports*.

TABLE 1—WEIGHTED AVERAGE PERCENTAGE CHANGE  
IN FLIGHT FREQUENCY BY HUB PAIR CLASSIFICATION  
1977-83

	Nonhub	Small Hub	Medium Hub	Large Hub
Nonhub	33.9	1.4	24.3	28.7
Small Hub		33.9	20.8	19.2
Medium Hub			-4.3	14.4
Large Hub				-3.5

cies of 9.2 percent. By way of comparison, aircraft departures increased by 1.5 percent. The increase in convenient connecting flights, leading to additional departure alternatives, is a result of a major change in airline operations. Under deregulation, airlines have adopted hub-and-spoke route structures, where travelers are fed via spoke routes into a major airport (hub) from which they proceed to take connecting flights to their destinations. Hub-and-spoke route structures were not developed fully under regulation because of entry restrictions and insufficient incentives, as perceived by management, to generate profit by a major restructuring of airline networks. Our results suggest that this change in operations contributed greatly to the success of deregulation. Because it is likely that the adoption of hub-and-spoke route structures is one of the major consequences of airline deregulation, it is of interest to analyze under what conditions, and for what modes, this type of route structure or alternative route structures is desirable.

## II. Intercity Transportation Route Structures

We illustrate our analysis of the conditions that favor hub-and-spoke route structures with reference to Figure 1, which represents a transportation carrier operating over a simple network. By regulatory authority, the carrier serves route 1 ( $A-C$ ) supplying output  $Y_1$ , (measured in passengers or tons of freight) and serves route 2 ( $B-C$ ) providing output  $Y_2$ . For simplicity, there is assumed to be no traffic on or regulatory authority to operate between the  $A-B$  segment. Under deregulation, the carrier faces three alternatives regarding the choice of optimal route structure that are of interest here. The carrier can

FIGURE 1

abandon service on one route (say route 1), it can maintain the same route structure as under regulation (status quo), or it can adopt a hub-and-spoke structure where traffic originating from  $A$  destined for  $C$  is routed through  $B$  and combined with traffic originating at  $B$  destined for  $C$ . The profit equations,  $\Pi^i$ , that correspond to these alternatives are

- (1)  $\Pi^1 = P_2 Y_2 - C(0, Y_2)$
- (2)  $\Pi^2 = P_1 Y_1 + P_2 Y_2 - C(Y_1, 0) - C(0, Y_2)$
- (3)  $\Pi^3 = P_1 Y_1^* + P_2 Y_2 - C(Y_1^*, Y_2)$ ,

with (1) being abandonment, (2) status quo, and (3) hub-and-spoke, and where  $P_i$  denotes price in market  $i$  (assumed constant across alternatives),  $C(\cdot)$  denotes total cost,  $Y_1^*$  denotes output from market 1 when routing traffic through the hub, and  $Y_1^* \leq Y_1$  because hub-and-spoke practices will increase travel time for traffic originating at  $A$  and thus possibly reduce output.<sup>3</sup>

We first consider the optimal route structure assuming two markets are to be served,

<sup>3</sup> In a more complicated network, traffic consolidation will increase the frequency of direct or connecting service relative to nonstop (point to point) service, thus possibly offsetting the effect of increased travel time.

and then examine under what conditions a carrier would abandon service. Given both markets are to be served, the criterion for adopting a hub-and-spoke route structure based on (2) and (3) is whether

$$(4) \quad C(Y_1, 0) + C(0, Y_2) - C(Y_1^*, Y_2) \\ > P_1(Y_1 - Y_1^*).$$

A hub-and-spoke route structure is thus desirable if the cost saving from producing output 1 jointly with output 2 (as opposed to producing output 1 independently) exceeds the possible loss in revenue.

A more complete understanding of this criterion can be obtained by considering the key determinants of  $C(Y_1^*, Y_2)$ . These joint costs will be reduced (increased) relative to independent production if the cost savings from economies of aircraft (or vehicle) size are greater (lower) than the cost of rerouting traffic. (In addition to the cost of increased distance traveled, more elaborate passenger or freight handling facilities will be required at the hubs.) That is, whether

$$(5) \quad C(Y_1^*|BC) + C(Y_2|BC) - C(Y_1^*, Y_2|BC) \\ > C(Y_1^*|AB + BC) - C(Y_1^*|AC),$$

where  $C(Y_1^*|BC)$  denotes the cost of transporting  $Y_1^*$  passengers (freight) on the route  $B$  to  $C$  and the other cost expressions are interpreted accordingly. The left-hand side of the inequality denotes vehicle size economies and the right-hand side denotes the cost of rerouting traffic.

To summarize, adoption of a hub-and-spoke route structure is warranted if scope economies are sufficient to offset any losses in revenue. The existence and magnitude of scope economies is a function of economies of aircraft (or vehicle) size and rerouting costs, while revenue loss depends on the resulting change in travel time (and frequency) and the users' relevant demand elasticities.

Generally, all modes are characterized by economies of vehicle size. (For discussions of these economies see Douglas and Miller for aircraft, Motor Vehicle Manufacturers Association, 1983, for buses and trucks, and

Theodore Keeler, 1983, for railroads.) These economies derive from more efficient use of labor and fuel associated with vehicles with greater capacity. Because of particular labor practices and vehicle dynamics, these economies are slightly greater for aircraft and trains, although buses and trucks exhibit significant vehicle size economies. For example, the Motor Vehicle Manufacturers Association reports that a 20 percent increase in productivity can be achieved by using double-trailer trucks instead of single-trailer trucks, while similar productivity gains can be achieved by using articulated buses instead of standard buses.

As a first approximation, rerouting costs are proportional to increases in travel distance for all modes. Thus, given that the potential for cost savings from hub-and-spoke operations appears to be similar across modes, the *relative* attractiveness of these operations depends largely on their effect on each modes' demand (i.e., revenue).

The final issue concerns whether a carrier should abandon service. Generally, a carrier should abandon service in a market if the fixed cost of operations exceeds the difference between the marginal revenue and corresponding marginal cost for that market. As illustrated in Richard Ericson and Winston (1983), the factors that can encourage a carrier to exit a market are, on the supply side, the presence of strong competition and rising marginal costs, and on the demand side, a high-market demand elasticity and a low price or weak demand.

It is now possible to assess or predict the impact of deregulation on various modes' route structures. Given air transportation technology, the change to hub-and-spoke operations is understandable: the economies of aircraft size that contribute to scope economies generally are not offset by revenue losses, because increases in travel time and travelers' corresponding responses are small (see our 1985 article). It is also interesting to note that the nature of hub-and-spoke operations can discourage abandonments because the benefits from these operations are derived from establishing and maintaining spoke routes to realize economies of aircraft size. Service is also preserved because major

airlines frequently coordinate with commuter airlines to serve cities with insufficient traffic to warrant service by the large aircraft used by major carriers.

The effect of the 1983 intercity bus deregulation legislation on route structure is likely to differ from the air experience. Bus technology does not appear to encourage the adoption of hub-and-spoke practices because any significant rerouting will increase travel time by a large amount and thus lead to a substantial reduction in patronage (see our 1985 article). This suggests that bus carriers are likely to abandon some routes under deregulation. That is, the most appropriate bus route structure is characterized by service of cities along a linear network. Some routes will not be economically justified for service and are thus likely to be abandoned.

Motor freight transportation was largely deregulated in 1980. Because deregulation eliminated vehicle routing restrictions, a hub-and-spoke type route structure has evolved significantly for less-than-truckload (*LTL*) service. Operationally, *LTL* shipments from several originating points are consolidated at major terminals (hubs) and sent out to their destinations. This practice is appropriate for motor freight transportation because economies of vehicle size are significant, while the cost of re-routing shipments is not excessive. Moreover, the increase in shipment transit time from this practice is not likely to reduce traffic substantially (see Winston, 1981). The adoption of hub-and-spoke type operations for *LTL* service has also preserved service on many routes.

Potential changes in the rail passenger transportation environment suggest our analysis may be useful in predicting future rail route structures. Currently, there is serious consideration of high-speed rail transportation in many parts of the country. In addition, latent concerns about rail passenger subsidies may eventually resurface and lead to the transfer of responsibility for regular rail service from the public to the private sector. In light of these possibilities, our analysis suggests that given the nature of rail technology, particularly the constraints imposed by the necessity of a fixed right-of-way, high-speed, and regular rail routes will corre-

spond to a linear network. Current routes that are not economically justified in such a network are likely to be abandoned. Rail route abandonments could be minimized if a modified hub-and-spoke route structure were developed, where bus transportation serviced passengers on spokes in combination with rail service on the main linehaul.

Finally, one of the major outcomes of the 1980 rail freight deregulation legislation has been the abandonment of service on many routes. As in passenger service, rail freight service is best carried out primarily for a linear network. It is possible, however, that many abandoned routes could eventually receive rail service through the development of coordinated rail-motor carrier hub-and-spoke type operations where motor carriers connect these routes with rail linehaul service.

The recent flood of transportation deregulation legislation will ultimately have different effects on modes' route structures. The benefits from deregulation depend significantly on how regulated route structures differ from optimal route structures. Some modes (air, motor carrier) have adopted hub-and-spoke operations that improve, or at least maintain, service to outlying (or low density) routes, while other modes (rail, bus) will develop their linear networks and abandon economically unjustified service to such routes. As a result, many shippers and travelers on outlying routes may have to depend on the development of joint modal operations to avoid a partial or total loss of their pre-deregulation transportation services. The actual value of such losses, should they occur, and their effect in assessments of the welfare effects of surface freight and passenger deregulation, await further research.

## THE END OF THE GREAT BOOM AND THE BREAKDOWN OF BRETTON WOODS: WAS IT A COINCIDENCE?<sup>†</sup>

### Macroeconomic Stability and Flexible Exchange Rates

By JOHN F. O. BILSON\*

During the past decade, the monetary approach to the theory of exchange rate determination has evolved rapidly in response to new empirical findings concerning the behavior of international financial markets. In addition to the founding assumptions of a stable money demand function and an exogenous money supply, the early monetary models relied upon three arbitrage conditions as market-clearing equations. The purchasing power parity condition integrated national commodity markets; the interest rate parity condition integrated national bond markets; and the forward parity condition provided an essential link between spot and forward markets by stating that the forward price was the market estimate of the future spot price. These arbitrage conditions distilled the complexity of a full general equilibrium model into a single equation which stated that the spot exchange rate was determined by the expected future path of the relative ratio of money to income.<sup>1</sup>

The purchasing power parity condition was the first victim of the empirical realities of the post-Bretton Woods system. Because of the magnitude of the variation in real exchange rates, and because the variation in exchange rates vastly exceeded the variation in relative commodity prices, it became obvious that the exchange rate did not clear the market by its indirect influence on relative prices and commodity flows. The failure of the price arbitrage condition was an im-

portant contributor to the development of the "asset market" approach in which financial markets were assumed to be "efficient" while commodity markets were characterized by sluggish price adjustment. The most widely used model of this type is, of course, Rudiger Dornbusch's model (1976) of exchange rate dynamics.

From the perspective of this paper, the most important result that Dornbusch derived was the "overshooting effect," in which sluggish price adjustment in the commodity (and labor) markets resulted in increased variability in exchange rates and interest rates. The result is important because it demonstrated that the instability of the floating rate system could be due to the inherent differences between commodity and financial markets. This view stands in strong contrast to the libertarian consensus which attributes all of the instability of the system to the irrational practices of the public participants in the market.

Both the asset market and monetary approaches relied upon the forward parity condition as the link between current and expected future prices. If the forward price could be assumed to be a market forecast of the future spot price, then the techniques developed in the rational expectations literature could be used to find concise expressions for the relevant endogenous variables. For those with an empirical bent, the forward parity condition became the next target after the purchasing power parity theory had been beaten to death.

Since it is impossible to exactly determine the expected future spot rate, it is empirically more difficult to reject the forward parity condition. However, as the number of observations has increased and as econometric techniques have become more sophisticated,

<sup>1</sup>For a review of these models, see my article (1979).

the validity of forward parity has become increasingly questionable. The forward premium, the logarithmic difference between the forward and spot exchange rates, can be tautologically divided into a risk premium and an unbiased forecast of the rate of change in the exchange rate. The forward parity condition assumes that the major part of the variation in the premium is due to the forecast element, and that international risk premia are small and stable over time. The new empirical evidence rejects this view and replaces it with the empirical paradigm that most of the variation in the premium reflects variation in the risk premium rather than variation in the expected rate of appreciation.<sup>2</sup>

This finding shall form the basis of this paper's analysis of the instability of financial prices under floating rates. Specifically, the object of the paper is to determine if the failure of the forward parity condition is a cause of instability in the same way that the failure of purchasing power parity is a cause of instability in the Dornbusch model. In order to investigate this issue, it is necessary to first define the failure of forward parity in a more specific manner.

Consider the following regression equation:

$$(1) \quad s_{t+1} - s_t = \beta(f_t - s_t) + u_t,$$

where  $s(f)$  represents the log of the spot (forward) exchange rate,  $\beta$  is a regression coefficient,  $u$  is the residual, and  $t$  is an index of time which, for this discussion, shall be assumed to be measured in units of one month. It is also assumed that the residuals are identically and independently distributed. Equation (1) can be considered as a composite forecast of the future spot rate. The composite includes the current spot rate, which would be the appropriate forecast if the exchange rate evolved as a random walk, and the forward rate, which would be ap-

propriate if the forward parity model was correct. Within this interpretation, the regression coefficient may be interpreted as the weight on the forward rate in the composite forecast.

Recently, Eugene Fama has suggested a different interpretation of this equation. Using the decomposition of the forward premium into its risk premium and expectational components, Fama demonstrates that the regression coefficient may be used to determine the relative variability of the two components. If the estimate is unity, then all of the variation in the premium may be attributed to expectations; if it is zero, then all of the variation in the premium can be attributed to variation in international risk premia.

The recent empirical evidence has led to a reasonably firm rejection of the hypothesis that the true value of the  $\beta$  coefficient is unity. Based upon my own subjective review of the literature, my prior mean for  $\beta$  is about .2 with 95 percent confidence limits ranging from -.3 to .7. It is consequently not possible to reject the view that the forward premium, and hence international differences in short-term interest rates, are unrelated to either actual or market forecasts of exchange rates. The next major task for exchange rate theorists, then, is to develop an alternative model of the determination of the premium and to incorporate this alternative into the existing literature on exchange rates.

My purpose in this presentation is more limited. The question that I wish to address is the following: if the forward parity assumption was correct, would spot exchange rates and forward premia be more or less stable? The issue can also be stated negatively: has the failure of forward parity been an independent cause of financial volatility? My starting point is the standard asset market reduced-form equation:

$$(2) \quad s_t = z_t + \phi(f_t - s_t),$$

where  $z_t$  represents the current fundamental influences on the exchange rate. (In the monetary model,  $z_t$  is equal to the relative money to income ratio of the two countries.) If the exchange rates are quoted in dollar

<sup>2</sup>My paper with David Hsieh (1984) and that by Eugene Fama (1984) present estimates of the equation in the text. There are many papers with estimates of similar equations.

terms,  $f_t - s_t$  is the forward premium on the currency from a dollar perspective. Since a positive forward premium implies a lower local interest rate and hence a lower opportunity cost of holding the currency, it is reasonable to assume that the  $\phi$  parameter is positive. If we assume that  $\phi$  is equal to Cagan's semi-elasticity, and that the interest elasticity of the demand for money is .15 when nominal interest rates are 1 percent per month, then the value of  $\phi$  should be around 15. This estimate will prove useful in the discussion below.

Combining equation (2) with expectations of the future spot rate formed on the basis of equation (1), the spot rate can be expressed as a combination of the current fundamentals,  $z_t$ , and the expected future spot rate,  $E_t s_{t+1}$ :

$$(3) \quad s_t = (1 - \gamma)z_t + \gamma E_t s_{t+1},$$

where  $\gamma$  is defined as  $(\phi/\beta)/(1 + (\phi/\beta))$ . For positive  $\phi$ , it is clear that increases in  $\beta$  result in a decrease in  $\gamma$ . In effect, higher values of  $\beta$  are similar, in their effect on the exchange rate, to decreases in the interest elasticity of the demand for money.

In order to complete the model, an assumption must be made concerning the process generating the forcing series,  $z_t$ . For illustrative purposes, assume that the rate of growth of the forcing series is determined by a first-order autoregressive process:

$$(4) \quad \Delta z_t = \alpha \Delta z_{t-1} + v_t.$$

This type of process typically "fits" series like the money supply that are candidates for fundamental variables influencing the exchange rate. Since the procedures for solving equations like (3) with forcing series generated by (4) are well known, only the final results will be reported here. For the exchange rate, the solution is presented in equation (5):

$$(5) \quad s_t = z_t + \frac{\gamma\alpha}{1 - \gamma\alpha} \Delta z_{t-1}.$$

Combining (5) with (2), the forward pre-

mium can be expressed as

$$(6) \quad f_t - s_t = \frac{\gamma\alpha}{\phi(1 - \gamma\alpha)} \Delta z_{t-1}.$$

By combining (6) with (4), the forcing series may be expressed as a first-order autoregressive process:

$$(7) \quad f_t - s_t = \alpha(f_{t-1} - s_{t-1}) + (\gamma\alpha/\phi(1 - \gamma\alpha))v_t.$$

This equation has two important implications. First, it demonstrates that the autocorrelation in the forcing series may be estimated from the autocorrelation in the forward premium. Based upon monthly observations, a reasonable estimate of  $\alpha$  from the floating rate period is about .8 if a constant is included in the equation. Since all of these equations should be considered to be referring to deviations around stable trends, this estimate is appropriate for our purposes. Second, the influence of the failure of the forward parity term on the volatility of the premium can be examined through the term  $(\gamma\alpha)/\phi(1 - \gamma\alpha)$  which translates the innovation in  $z_t$  into the innovation in the premium.

Combining (1), (4), and (5) yields an expression which decomposes the change in the spot rate into its anticipated and unanticipated components:

$$(8) \quad \Delta s_t = \beta(f_t - s_t) + \frac{1}{1 - \gamma\alpha} v_t.$$

With these equations in hand, it is now possible to examine the effect of the failure of the forward parity condition on the volatility of the exchange rate and the forward premium. Using the estimated values of the key parameters, the following estimates of the volatility terms can be obtained.

	$\beta = 1$	$\beta = .2$	Ratio
Exchange Rate: $\frac{1}{1 - \gamma\alpha}$	4.00	4.75	1.19
Forward Premium: $\frac{\gamma\alpha}{\phi(1 - \gamma\alpha)}$	0.2	0.25	1.25

These results can be interpreted in the fol-

lowing way. Under forward parity,  $\beta = 1$ , the standard deviation of the exchange rate will be 4 times the standard deviation of the forcing series. This "magnification effect" reflects the discounting of the change in the anticipated future growth of the series into the current spot price. With  $\beta = .2$ , the market requires a larger premium to accommodate any given change in expectations, the premium itself influences the spot rate through its direct influence on interest rates and the change in the exchange rate is exacerbated. With  $\beta = .2$ , the standard deviation of the exchange rate is 4.75 times the standard deviation of the forcing series. Relative to the forward parity model, the standard deviation of the exchange rate is almost 20 percent higher.

Similar results are obtained for the forward premium. With forward parity, the standard deviation of the premium is estimated to be 20 percent of the standard deviation of the forcing series. With  $\beta = .2$ , this estimate increases to 25 percent. Hence the estimated effect of the risk premium is a 25 percent increase in the variability of the interest rate. In most models of this type, the adjustment to an innovation is shared between the spot price and the premium so that an increase in the variability of one variable should be associated with a decrease in the variability of the other. This is not the case in the present instance.

In the preceding discussion, I have attempted to build a formal link between the empirical results on currency risk premiums and the variability of exchange rates and interest rates. The argument is closely related to Ronald McKinnon's (1979) conjecture that the instability of the floating rate system is due to "insufficient speculation" and to Stanley Black's (1984) exposition of the Harrod effect. Rather than viewing speculation as a source of instability, this literature accepts that speculative activity is stabilizing and argues that the floating exchange rate system inhibits stabilizing speculation. For the remainder of the paper, I will expand upon this theme with some comments and empirical observations.

One useful way to consider the risk premium argument is to view foreign exchange

speculation as an investment activity. William Sharpe (1983) has suggested that the performance of investment advisors can be summarized in the statistic  $\bar{r}/s$ , where  $\bar{r}$  is the average excess return and  $s$  is the standard deviation of the return. For the broad U.S. equity indices, the Sharpe ratio for monthly observations over the postwar period has been estimated to be around .15. Under the assumption that the actual exchange rate follows a random walk, and that the monthly standard deviation is 3 percent, the interest rate differential would have to be 5.4 percent in order to offer the same prior risk/return tradeoff as the market average.<sup>3</sup>

This appears to me to be a wide range. If U.S. interest rates were 10 percent, foreign interest rates could range between 4.6 and 15.4 percent before offering a risk/return tradeoff that was comparable to traditional equity investments. It is also interesting to note that this range encompasses most of the actual interest rates observed on different currencies when U.S. rates were around 10 percent. If major investment institutions required a risk/return tradeoff on foreign currency investments that was at least equal to that on traditional investments, then we would expect that there is a wide range in which interest rates are predominantly determined by domestic factors.

This does appear to be the case. In the absence of currency risk, interest rate differentials should reflect the expected change in the exchange rate. At the other extreme, the interest rate differential between two closed economies should reflect the difference in their expected inflation rates (given similar real rates). A number of studies have demonstrated that nominal interest rate differentials are significant predictors of inflation rate differentials. Discussions in the financial press also invariably attribute changes in U.S. interest rates to domestic, rather than international, considerations.

<sup>3</sup>It is necessary to qualify this risk/return tradeoff argument in two ways. First, the tradeoff may be substantially improved by various portfolio selection techniques. Second, the market or consumption risk of currency speculation may be low relative to the absolute risk.

This argument should not be taken too far. The high nominal interest rates in the United States over the past two years have attracted capital and led to an appreciation of the dollar. The real overvaluation of the dollar has permitted the United States to endure interest rate differentials beyond the 5 percent mentioned above by creating expectations of a future depreciation of the dollar. An interest rate of 8 percent, for example, would attract capital according to the 5 percent rule if the expected depreciation of the dollar was less than 3 percent. This example illustrates why the forward parity regressions yield coefficients that are less than unity. In this case, a 3 percent expected depreciation is associated with an interest rate differential of 8 percent, yielding a  $\beta$  estimate of .38.

The currency risk premium results in a partial segmentation of financial markets. This view may seem to contradict the idea that foreign financial markets offer the opportunity to diversify away purely domestic risk. However, recent estimates by Michael Adler and Bernard Dumas (1983) have shown that the minimum variance portfolio for any individual consists almost entirely of short-term financial instruments denominated in the home currency. In order to be induced to hold riskier investments, the individual must be reasonably confident that the expected return compensates for the risk. There is a great deal of evidence that supports the higher return on risky domestic investments, but there is little evidence to support the view that foreign investments, and particularly foreign currency speculation, has an expected return sufficient to compensate for the risk of the activity.

The currency risk premium is an important factor in considering the relative merits of fixed and floating rate systems. With a fixed exchange rate, financial shocks in a particular country are spread throughout the system and interest rates are linked through the interest rate parity condition. The floating rate system, in contrast, has created a financial environment in which interest rates are predominantly determined by domestic conditions and movements in the exchange rate are dominated by nonspeculative activity. The absence of speculative

activity, particularly activity based upon longer-run fundamentals, may be an important factor contributing to the instability of the system.

I take it to be self-evident that exchange rate and interest rate instability have adverse effects on the world economy. Statistical studies have demonstrated that innovations in nominal interest rates are the primary causal factor (in the Granger sense) in the U.S. business cycle. To the extent that real interest rates have increased to compensate for the risk, the instability has created a painful transfer of wealth between debtors and creditors both domestically and internationally. The combination of real exchange rate instability and real interest rate instability has had particularly adverse effects on the Third World.

A return to a system like Bretton Woods would be one answer to the issues raised in this paper. There are, however, other alternatives that should also be explored. These include tying the value of the dollar to a specific bundle of commodities or creating a new money whose value is determined by an underlying portfolio of real assets. All of these approaches should be considered. For the moment, all that can be done is to recognize that there are many characteristics of the floating rate system that we have yet to understand, let alone control.

# Reflections on the Exchange Rate System

By J. CARTER MURPHY\*

It is tempting to compare the effectiveness of fixed and flexible exchange rate systems by contrasting the performance of the world economy under the original Bretton Woods rules with economic performance since 1973. Coincidence of events in time, however, does not lead to an inference that the events are causally related. In fact, strong economic performance over a part of the IMF's first twenty-five years and poorer performance since that time are both the results of fundamental forces having little to do with fixed or flexible exchange rates. Here I shall briefly discuss those forces and then comment on proposals that would return us to some form of preannounced official targeting of the rates. This provides me an opportunity to raise some useful questions concerning the functions we want the exchange rates to perform.

## I. The Postwar Boom and Bretton Woods

In a book of a few years ago (1979) I detailed some causes of the breakdown of the original Bretton Woods arrangements, and in the limited space available to me here I must summarize that history. The policy choices of governments were dominated by inflationary biases from World War II to the late 1970's. During the 1950's, inflation was more endemic to Europe and the developing world than to North America, and the effects of the expansionary excesses abroad were offset by periodic devaluations of the inflated currencies against the dollar. When, in the mid-1960's, the United States became, among industrialized countries, the region with greater relative inflation, dollar devaluation against other currencies proved difficult for many reasons, and, in the end, the

gold exchange system centered on the dollar failed when flight from the dollar made the fixed gold-dollar exchange rate untenable. Subsequent efforts to restore currency par values at realigned exchange rates then proved impossible because governmental pledges to support pegged rates lacked credibility. The uneven inflation process was continuing, and inflationary expectations were on the rise.

The crux of the problem was that governments, quite predictably, responded to the constituencies that elected them (and with the limitations of their national political institutions), rather than to the requirements of a particular exchange rate structure whenever internal and external goals conflicted. The ragged inflation that resulted induced massive capital transfers in anticipation of changes in the par value exchange rates. In the end the violence of these transfers wrecked the system's tie to gold and made even continued fixed exchange rates on the dollar untenable for most countries.

To look back now with undue nostalgia on the Bretton Woods arrangements is, I think, a mistake. I like Peter Gray's (1974, p. 16) characterization of the Bretton Woods period as one in which the dollar moved from being an undervalued currency in the late 1940's and early 1950's to one roughly in equilibrium from the mid-1950's to the mid-1960's and finally to a position of overvaluation. In the first of these periods there was widespread discrimination against dollar goods and investments; in the second, progress was made toward trade and investment liberalization; the third saw a strong revival of protectionism in the United States and capital controls abroad.

The disorder that has plagued economic life during the *post*-1973 period of managed floating exchange rates is largely a legacy of the same inflationary excesses that brought the original Bretton Woods rules to an end. Considering older textbook predictions to

\*Department of Economics, Southern Methodist University, Dallas, TX 75275.

the contrary, it is ironic that the great inflation of the 1970's originated in the period of pegged exchange rates while the 1980's policies of disinflation have come in the period of floating rates. The structural maladjustments termed "stagflation" in the early 1970's were exacerbated by ill-fated efforts in Europe and North America to dictate wages and prices and then reinforced by the petroleum crises that began in 1973-74; all these were related to the chronic inflationary management of demand. While the uneven inflation (that supported real economic growth for a time but later became a source of distortion) cannot be blamed on the system of fixed exchange rates, it also cannot be attributed to floating. It was in fact due to economic ideas that concentrated too much on aggregate demand for current output and provided politicians an easy rationale for spending without taxing and for pegging nominal interest rates below equilibrium levels.

## II. Disillusionment with Flexible Exchange Rates

The disorders of the international economy since 1973 have made many economists disillusioned with managed floating and have led some to call for a return to pegging, or at least "targeting," the exchange rates (for example, John Williamson, 1983; Otmar Emminger, 1982; and Atlantic Council, 1983.) Excessive volatility in the rates is said to result from speculative activity based on changing expectations (or in some cases the absence of speculative activity), from lags in price adjustments following exchange rate changes, and from small short-run supply and demand responses to price changes. Protracted misalignments in the rates, an even more serious problem, are attributed to various causes including the following: 1) international capital transfers induced by macro- and microeconomic policies of governments; 2) public and private currency substitutions, motivated by changing appraisals of risks and returns in different currency denominations; 3) lags in sectoral price adjustments; 4) flow-stock mechanics in portfolio adjustments, in which initial portfolio balancing shifts are large relative to more permanent

redistributions of savings flows; 5) asymmetries in market access to information; 6) lagged price and quantity adjustments due to long-term contracts; and 7) oligopolies. (There are reviews of this literature in Williamson, and in Robert Dunn, 1983.) Such a list of complaints begs the question: what do we want the exchange rate system to do?

I believe we want the system: (a) to facilitate an international allocation of resources and pattern of trade that is "efficient"; (b) to encourage the movement of real and financial capital from points of lower to higher value; (c) to deal with systemic risks at low social cost and to assign the burdens of risk taking equitably; and (d) to adjust to disturbances in a low-cost way and to distribute the burden of adjustment costs equitably.

The desire for efficient resource allocation and trade does not imply that the exchange rates should be at purchasing power parity (*PPP*). The *PPP* calculations are behind most allegations of misalignment in the rates even when it is acknowledged that the rates must do more than achieve a goods and services market equilibrium. Williamson goes further than most when he defines a "fundamental equilibrium exchange rate" to be one which is "expected to generate a current account surplus or deficit equal to the underlying capital flow over the cycle, given that the country is pursuing 'internal balance' as best it can and not restricting trade for balance of payments reasons" (p. 14).

Still, what else might the exchange rate accomplish? Do we not want this price to reflect changing expectations as we want other prices to do? It is well established that speculative positions *correctly* taken in advance of uncertain events lead to actions which prepare for the event and have social value. While numerous studies have shown that forward (and, with interest parity, spot) exchange rates are imperfect predictors of future rates and are, to that degree, inefficient, have we experience that an officially targeted rate does better? Even though the "noise" of daily aberrations in a flexible rate is a nuisance, I am skeptical of the view that assumes experts have greater wisdom to gauge market tendencies than market participants have. While I have no difficulty

rationalizing small government interventions to interrupt exchange rate runs or to give depth to thin and hesitant markets, such interventions are very different from exchange rate targeting.

It is clear that exchange rates will "overshoot" their long-run equilibria when exchange rates are free to adjust rapidly while other adjustments in the system are slow. The relevant question is: is such overshooting uneconomic? Overshooting may accelerate other desired responses throughout the system, in the same way that Alfred Marshall (1890) saw his exaggerated short-term price adjustments inducing proper long-term adjustments of supply. Is not every market price in every real world adjustment part of what is at most a "second-best" solution, with the "first-best" solution denied by constraints on rates of adjustment of some variables? Have we much yet to say about the welfare properties of alternative adjustment paths in disequilibrium periods? In view of our ignorance on these matters, I see the evidence on overshooting as useful data on the dynamic properties of national economic systems, but not grounds for rejecting flexible exchange rates in favor of rates more fixed.

Let us turn next to the roles the exchange rate plays in directing real flows of investment. For investment flows to be efficient, it is not required that they be from regions where fixed capital is relatively abundant toward regions where fixed capital is scarce, or from "rich" countries to "poor." The allocation of saving, and also the portion of the existing capital stock that is liquid, is directed by its price and the expected variance of that price. These values are sensitive in different regions to changing time preferences, changing liquidity supply and demand, and changing perceptions of risk, as well as to changes in the efficiency with which investment contributes to the production of goods.

When there are changes in one country's excess demand for liquidity, time preference, or apparent ability to provide safety to capital returns, as compared to other countries, it is, in my view, efficient from a global perspective for capital to move toward the area of

improved or safer returns. One may want to distinguish analytically between changes that originate in the private sector and those that are implemented through government policies—changes in money demand as opposed to government controlled money supply, for example, or changes in aggregate time preference resulting from individuals' savings choices as opposed those due to government managed income redistributions—and I return to this matter below. But I think one should not deny that capital movements induced by changing time preferences, liquidity adequacy, and perceptions of security are "appropriate" and that the exchange rates that accommodate the transfers are efficient rates.

The allegation that recent movements of capital to the United States have sought, among other things, a "safe haven," suggests, however, a further point. The safety sought by these investors has been perhaps in some degree safety from expropriatory governmental regulation. While confiscatory risks are real enough to individuals or firms as investors, they refer to wealth transfers, not losses, from the viewpoint of nations and the world as a whole. If international transfers based on this fear, then, are to be considered socially efficient, the rationale must be in terms of individual liberty and the importance of property rights rather than in terms of other needs.

The subject of risk in the economy, and who should bear it and how, is an especially difficult one, but it is an issue in arguments over the exchange rate regime. When the foreign exchange rate is held within a pre-designated range by official intervention, risks in the system are transferred from some in society to others. Awareness that intervention will prevent a currency's depreciation, for example, relieves those who would be directly affected by such a change (users and producers of internationally traded goods and holders of money and nominal money claims). It also increases risks to others—at home and abroad—including those for whom the likelihood rises that governments will use alternative policy measures to deal with the balance of payments. While the provision of reserve assets for the world economy as a

whole need not be costly (if fiduciary rather than "real" assets are used for this purpose), and even the holding of reserves by one country is costly only in the degree that the reserves are held in assets which yield less return than optimal real investments, use of reserves by any government is costly to those who must forego absorption when the reserve stocks are rebuilt and to those whose absorption is impaired by trade at an officially selected but inappropriate exchange rate. Exchange market intervention by governments, therefore, does not reduce risk; it reassigns it (Milton Friedman, 1953).

A flexible exchange rate spreads adjustment burdens—and the risk of uncertain burdens—*between* countries more than does a stabilized rate because with stabilized rates deficit countries more commonly have to initiate policy changes. On the whole, greater international participation in such burden sharing is probably desirable on grounds of spreading the costs and their attendant risks as widely as possible. One cannot be unequivocal about even this, however, since it can plausibly be argued that adjustment burdens resulting from "bad" policies should be borne in the country responsible for the bad policies, where the policies can be changed.

Business people have deplored since 1973 the increased risks of international trade and investment they have been asked to bear. We are told of the multifaceted adjustments they have made to minimize the costs of their new risks (for example, Marina Whitman, 1984). I do not, however believe that the fact that these burdens and adjustments are being borne by traders and investors is a proper argument against flexible exchange rates. The exchange rate has been described as a "system variable par excellence" (Val Koromzay et al., 1984); it reflects changes that have occurred, are occurring, or are expected to occur in many parts of the world economy. Might it not be best for the uncertainty surrounding these events to be borne, in the first instance, by those most likely to have information about them? In particular, is it not desirable that they be borne to the maximum extent possible by those persons who have less risk aversion and are willing to take

speculative positions in the market, rather than by those who are passive gainers or losers from governments' successes or failures as exchange speculators? Broad price level changes—and their risks and burdens—that accompany significant exchange rate swings are of course passed on by traders in a flexible rate regime; the evidence nevertheless is clear that the effects of many small exchange rate moves are absorbed by the professionals in such a setting. Generally, I feel that risk taking ought to be a market activity, rather than a socialized one, except where significant externalities can be demonstrated.

### III. Which System Best Bears Shocks?

How does the system bear shocks, and can anything be said about the contributions of alternative exchange rate regimes in this connection? Clearly neither fixed nor flexible exchange rates is best at minimizing adjustment costs to *all* types of disturbance. One must, therefore, weigh the seriousness of disturbances the system must absorb and consider what exchange rate design copes best with the more serious shocks. In this vein I suggest that by far the most damaging disturbances to international economic equilibrium during the past forty years have emanated from the public sector, not the private. While many of us were raised in an era in which it was accepted that the *private* sector was the source of economic instability and the *public* sector was the home of policy instruments for countervailing the private sector disturbances, I am sadly driven to doubt the old views. Perhaps a time will come when democratic governments will tax and spend and manage money in a way that is stabilizing to society. But experience since World War II suggests that we should give thought to system designs that absorb shocks from this area as well as the private sector. Furthermore, it is worth noting that to seek a system that protects one national economy from unexpected policy shifts in another is not the same thing as desiring a system that facilitates as much as possible governmental use of the macroeconomic policy instruments.

The ease with which one or another exchange rate regime handles the macroeconomic aspects of public policy disturbances depends, in the first instance, on the way the regime handles the international capital transfers involved, as the asset approach to exchange rate determination has shown us. Now the important thing about a flexible exchange rate regime is that in it net transfers of capital claims immediately become real transfers because international net sales of capital claims affect exchange rates and generate current account surpluses or deficits to mirror the claims flow. In a system where the exchange rate is wholly or partly stabilized, on the other hand, international shifts in capital claims are wholly or partly financed by reserve transfers, avoiding to that degree a disturbance to production and trade. This is, I think, a central argument for stabilized exchange rates, and it is applicable when disturbances are temporary and of sufficiently small magnitude that they can be financed by modest monetary reserve movements. Where a disturbance is large and enduring, a flexible exchange rate is almost certainly preferable because it avoids the production and consumption distortions that are due to a too long maintained nominal exchange rate, and it provides a useful degree of flexibility to real prices and wages at home and abroad.

Since, of course, no one knows whether a government policy change is going to be large or durable until after the event, one must consider the costs involved in a wrong forecast. What is clear here is that the very costly adjustments are the large ones, and they are the ones that must not be missed. Failure to recognize and accommodate them early enough was a critical weakness in the Bretton Woods arrangements. It is this line of thought that persuades me we must have a system among the industrialized countries that has a significant degree of exchange rate flexibility.

Correct expectations and speculation on those disturbances that prove reversible can give even a flexible exchange rate regime the advantages of a fixed rate system. Incorrect expectations or inadequate speculation, on

the other hand, expose the weaknesses in the flexible system. Exploration of crawling rate systems (see my 1965 article) and other compromise arrangements should not be ruled out. But a high degree of exchange rate responsiveness to market pressures is, I believe, an important safeguard against delaying real economic adjustments too long.

#### IV. Containing Public Sector Shocks

It is clear from much of the literature on exchange rate arrangements that the authors seek global adjustments to disturbances that arise in the private sector but minimal external accommodation of disturbances from the public sector. It is not clear to me that all shifts in public sector actions have any less claim to accommodation through world market adjustments than have private sector shifts. Yet the view that one government should not impose the results of its economic policy choices on other nations is widely accepted. It is, I think, the basis for the lament seen in recent economic writings (Whitman; Dunn) that floating exchange rates have not secured isolation for national economies from external changes, and it is the justification for the grant by governments of surveillance authority to the IMF to inhibit beggar-thy-neighbor policy choices. The truth probably is that we don't want bad policies exported, but we do want good policies shared.

Is there any institutional arrangement that, without too great cost, will contain the macroeconomic effects of all government monetary and fiscal changes? Clearly a regime of floating exchange rates will not do so alone, although in a more naive age there was hope for it. Severe restrictions on international capital movements would protect the current account in a flexible exchange rate setting but would be unable to distinguish between government induced capital movements and those serving strictly private sector needs; they would also raise a harvest of other problems. The IMF surveillance of nations' economic policy mixes with a view to discouraging clear beggar-thy-neighbor choices can be helpful, but the IMF's ability to in-

fluence the policies of major countries so far remains small (William Hood, 1982).

One promising guideline for evaluating governments' macroeconomic policy choices calls for fiscal and monetary changes to be "balanced." Equal proportional changes in a nation's monetary base and in face value of public debt instruments outstanding (by maturity class) would go far toward neutralizing the impact of demand management changes on real interest rates in the nation where the changes take place and hence on induced international capital transfers. In a regime of flexible exchange rates, any nation, or all nations simultaneously pursuing such a rule, could follow expansive or restraining overall monetary and fiscal policies of their choice without disturbing the international current and capital account balances much (see my book, 1979). Yet the markets would remain free to accommodate shifts in costs and private preferences of all kinds. Under fixed exchange rates, the monetary-fiscal policy mix of each country is pulled automatically toward the balance of other countries because money stocks move internationally toward countries with the lowest ratio of money to debt growth. But this alone does not prevent policy shifts in one country from impinging upon others.

I do not hold out much hope in the near future for guidelines calling for fiscal and monetary balance because fiscal policies are the result of microeconomic political pressures as much as of macroeconomic needs, and central banks will, for reasons, some of which are good, be reluctant to yield up their independence to pursue their own policy objectives. Nevertheless, if we continue to have activist government policies and at the same time wish to limit their impact abroad, we must create new images for the public concerning what constitutes good policy. In this case, flexible exchange rates with monetary and fiscal policy balance provides one of the few packages around that is deserving of consideration.

# On the System in Bretton Woods

By JOHN WILLIAMSON\*

It has become customary to look back with nostalgia at the golden age when the Bretton Woods system held sway, from the early 1950's to around 1970. It also seems to be the conventional wisdom, however, that the rules of Bretton Woods contributed little to the impressive performance of the world economy over that period—a performance characterized not merely by the fastest and most widely distributed growth in history, but also by notable stability, including near price stability except at the beginning and end of the period. The deterioration in the performance of the world economy since the early 1970's is viewed as a coincidence, or a response to common causes, rather than as a consequence of the breakdown of Bretton Woods. My purpose in selecting the title to this session was to induce critical scrutiny of these conventional attitudes.

My own contribution to this task will start by describing what I conceive to have been the three essential rules of the Bretton Woods system. I shall proceed to examine the logic of those three rules in terms of recent contributions to the literature, in particular the emergent literature on policy coordination, and of recent historical experience.

## I. Three Central Rules of Bretton Woods

An international monetary system comprises an exchange rate regime, rules governing the policies that are to be used to adjust payments imbalances, and a reserve supply mechanism to provide assets in which payments imbalances are settled.

Bretton Woods adopted the adjustable peg. *Exchange rates* were normally to remain sta-

ble within narrow margins, but could, and by implication should, be changed when there was a "fundamental disequilibrium." Although never formally defined, and therefore a target for much critical academic comment, there was never much doubt what this concept meant: a situation in which a country could not expect to achieve basic balance over the cycle as a whole without deflating output from full capacity or restricting trade or payments for balance of payments reasons. Thus the basic principle embraced was that exchange rates should be directed toward medium-run balance of payments needs rather than short-run anticyclical policy. The motivation was quite explicitly that of outlawing the beggar-thy-neighbor use of exchange rate policy that had occurred in the 1930's.

The IMF Articles adopted at Bretton Woods were not comprehensive in their specification of the practices that were to govern *balance of payments adjustment*. For example, there was no explicit specification of which country should initiate adjustment, or when. Exchange rates could be adjusted when there was a significant medium-run imbalance. Reserves were to be used to avoid the need for continuous external balance. It was universally assumed at the time of Bretton Woods, though not formally spelled out, that fiscal and monetary policy would be directed at the maintenance of full employment (or "internal balance"). But by the absence of alternative provisions to deal with modest non-self-reversing imbalances, one infers that the architects of Bretton Woods accepted that it would be necessary to shade fiscal-monetary policy with a view to the balance of payments position.

Although Keynes did not get the negative interest rates on creditor *bancor* positions that he sought, the *reserve regime* did imply something about the assignment of adjustment responsibilities. Countries were expected to restrict their deficits to the sums

\*Senior Fellow, Institute for International Economics, 11 Dupont Circle, NW, Washington, D.C. 20036. I acknowledge constructive comments on a previous draft by Matthew B. Canzoneri, William R. Cline, Michael Jones, Stephen Marris, and Robert Solomon; the usual caveat applies. © Copyright 1985 Institute for International Economics. Published here by permission.

that could be financed from their available reserves supplemented by IMF drawing rights. Reserve currency countries (*sic*) had some additional latitude to finance payments deficits by issuing their own currencies, but it was assumed that this possibility would be limited by the need to maintain confidence in convertibility. Bretton Woods ratified the gold-exchange standard, it did not legislate a dollar standard. (The special position of the dollar was confined to the obligation to defend a par value in terms of gold rather than in terms of another currency.) Britain invested much energy in gaining an assurance that the United States would participate in the adjustment process (and secured the scarce currency clause to that end), which would have been anomalous in a dollar standard world.

In my interpretation, Bretton Woods was far more than just a commitment to pegged exchange rates, as has sometimes been claimed (for example, see Ralph Bryant, 1980, p. 475; Robert Solomon, 1984, p. 174). It embodied, rather, a comprehensive set of rules for assigning macroeconomic policies: exchange rates to medium-run external balance, fiscal-monetary policy to short-run internal balance, and reserves to provide a buffer stock (as distinct from a monetary base) that would allow short-run departures from external balance. This is the intellectual position that Keynes had developed in the interwar years, which in my view probably explains why he used his influence to secure British ratification of Bretton Woods despite his bitterness at the across-the-board rejection of the plans for postwar reconstruction that he had nurtured during the war years (see my 1983a article).

## II. Implications of the Bretton Woods Rules

A vast literature developed in the 1960's on the ills of the Bretton Woods system. These were classified under the headings of the problems of adjustment, liquidity, and confidence. This is not the place to review those topics, save to say that this classification became such a part of the conventional wisdom that it has sometimes been used as a framework within which to evaluate *any* in-

ternational monetary system. This is misguided. One may agree that adjustment, liquidity, and confidence are all handled better by present arrangements than they were by the Bretton Woods system, but nevertheless believe that *other* problems with present arrangements outweigh those gains. What seem to me the dominant problems with these arrangements are (a) their propensity to generate exchange rate misalignments, (b) the absence of any discipline on national overspending less drastic than the credit-worthiness constraint that has now replaced the liquidity constraint, and (c) the lack of pressure they exert to coordinate policies. One may ask, with the benefit of hindsight, why these were *not* problems with the Bretton Woods system.

*Exchange rate misalignments* remained modest for most of the Bretton Woods period. The first rule of the system said that a misaligned rate (using that term as a pseudonym for fundamental disequilibrium) could be adjusted to eliminate the misalignment. One objective of the advocates of limited flexibility was to transform this *right* to change a misaligned rate into a positive *duty*. In the absence of such a duty, and in the presence of the pressures that the adjustable peg created to declare rates permanently fixed (so as to discourage speculative attacks), some substantial misalignments—especially of the reserve currencies—emerged by the second half of the 1960's. However, even these misalignments were smaller than those witnessed in recent years. Misalignments emerged from differential inflation and productivity growth, but not from exchange rate movements: indeed, since markets knew that governments would change par values only when they judged this appropriate on the basis of long-run fundamentals, speculative pressures acted as a check on the size of misalignments, rather than as a cause of them.

There is in my view a presumption that the vast exchange rate misalignments of recent years have had some negative effect on growth (via the promotion of deindustrialization in countries with overvalued currencies) and also some effect in ratcheting up inflation (see my 1983b study). These effects are,

admittedly, not well documented, though the supposed negative tests of the ratchet hypothesis are unpersuasive since they did not search for a ratchet effect on wages.

The virtues of a *liquidity constraint*, which resulted from the limited mobility of capital, were not always appreciated during the days of Bretton Woods. As recent work by Michael Jones (1983) has shown, however, a reserve constraint can substitute for explicit policy coordination, a theme discussed further below. The social function of a reserve constraint is there interpreted as that of disciplining macroeconomic policies so as to limit and make more predictable the demand and monetary spillovers received from abroad. In a world where policymaking is often myopic, the displacement of the former liquidity constraint by a creditworthiness constraint is not necessarily advantageous even from the standpoint of the individual country involved. Under Bretton Woods, countries suffered speculative attacks when their par values came to look vulnerable, instead of being able to pursue unsustainable policies for years while building up a vast mountain of foreign debt. That ability has already led Latin America into a devastating debt crisis, and it is now permitting the United States to pursue a policy course equally fraught with danger. Extensive capital mobility on the scale of the past decade is like fiat money: a social innovation with potential for great good, which in fact has almost certainly detracted from human welfare.

Overt (sometimes described as "continuous") *policy coordination* does not seem to have been much more effective in the golden age of Bretton Woods than it is in the days of Reaganomics. Hence the claim that Bretton Woods secured a useful measure of policy coordination has to rest on a demonstration that it was a successful case of what Richard Cooper calls a "rule-bound regime" (1985, p. 1226). That is, that the Bretton Woods rules were such as to ensure that spontaneous pursuit of national self-interest subject to continued observance of the rules ensured a broad consistency between national and world interests.

There is by now a significant literature showing formally that choice of monetary

and fiscal policies with a view to short-run stabilization objectives (maximization of a utility function specified in terms of the activity level and inflation and/or the balance of payments on current account), taking other countries' policies as given and with exchange rates flexible, leads to an outcome (the Nash equilibrium) inferior to that available with policy coordination (the cooperative solution). See Matthew Canzoneri and Jo Anna Gray (1983), David Currie and Paul Levine (1984), and Gilles Oudiz and Jeffrey Sachs (1984). The first two of these three contributions investigate explicitly the merits of a fixed exchange rate rule as a way of ruling out manipulation of the monetary/fiscal mix with a view to gaining short-run benefits at the expense of other countries, and conclude that this constraint can indeed be mutually beneficial. The first of the Bretton Woods rules introduced precisely this constraint, but in a form that did not preclude an exchange rate change needed to facilitate payments adjustment.

The objective of precluding the manipulation of exchange rates as instruments of short-term anticyclical policy was indeed deliberately sought by the architects of Bretton Woods, with the experience of competitive devaluations in the 1930's in mind. Has experience since 1973 shown comparable evidence of antisocial behavior? To answer that question one has to know whether it is appreciation or, as in the 1930's, depreciation (relative to the *PPP* trend) that will have an adverse impact on other countries. Canzoneri and Gray have postulated that it is structural characteristics in the world economy, such as the degree of wage indexation and whether the oil price is fixed in terms of a particular currency, which determine whether the spillover benefits of monetary expansion on other countries are positive or negative. My own hypothesis would be simpler; that this depends primarily on whether unemployment or inflation is perceived to be the dominant problem confronting policymakers. In the 1930's, depreciation was antisocial. But when inflation is perceived to be the dominant problem, as in general since 1973, complaints will center on competitive appreciation—as they did in the debate on vicious and virtu-

ous circles in the mid-1970's, and in the reaction of Europe and Japan to the dollar appreciation of the early 1980's. The recent muting of European complaints on this score may reflect growing recognition that the problem of the decade in Europe is unemployment.

The second of the Bretton Woods rules as interpreted above assigned monetary-fiscal policy to short-run internal balance, subject to the need to maintain the exchange rate peg. As long as the basic presupposition of Keynesian demand management, that price levels are constant (or at least predetermined), remained approximately valid, this worked rather well: with hindsight, fine-tuning surely has to be rated a greater success than it was at the time. And as long as exchange rates remained properly aligned, the "stop-go" policies imposed on demand management by the Bretton Woods constraints served a social function that few appreciated at the time (but see Robert Triffin, 1960, pp. 82-83, for an exception). With a correctly aligned exchange rate, an external deficit provides an early warning that deflation is needed, while the automatic stabilizer provided by the deflection of excess demand into an external deficit constitutes a safety valve that helped prevent the development of inflationary inertia.

The third of the Bretton Woods rules required countries to respect a (reasonably symmetrical) reserve constraint, while using reserves as a buffer stock to reconcile continual pursuit of internal balance with only medium-run pursuit of external balance. The major benefit that arose from this rule, in conjunction with the first two, is that it helped to avoid a synchronized world business cycle. Robert Lawrence (1978) found that there was practically no synchronization during the period 1959-67 when the Bretton Woods system was functioning properly, with adequate but not excessive liquidity. There was synchronization in an earlier period, 1950-58, which he explained by a liquidity shortage that forced other countries into following the United States, especially during and after the Korean War. The recession of 1958 was the one case of a synchronized (but nonetheless relatively mild) world recession during

the Bretton Woods period. Thereafter until 1969 recessions were essentially national, induced primarily by a need to curb payments deficits: France in 1959; the United States in 1960; Britain and Canada in 1962; Italy in 1963-64; Japan in 1964; Germany in 1966. Under the Bretton Woods rules, other countries tended to offset those recessions by expanding demand so as to preserve internal balance when exports fell, while one country's deficit (that pushed it toward restraint) was another's surplus (which nudged it toward monetary expansion). Thus the world as a whole did not deviate significantly from full employment because of payments imbalances. The mechanism that was supposed to secure this result under the gold standard (though it is doubtful whether it did—Barry Eichengreen, 1984) seems actually to have functioned during the golden age of Bretton Woods. Advocates of a dollar standard, such as Charles Kindleberger (1981), never gave sufficient weight to the loss of this mechanism that would follow abandonment of a U.S. reserve constraint. (That constraint *did* have an impact on U.S. policy: witness John Kennedy's nightmares about a rise in the price of gold, Operation Twist, and the 1968 tax increase.)

The evidence of Lawrence and Alexander Swoboda (1983) reinforces casual retrospection and an examination of the reference cycles of the Center for International Business Cycle Research in confirming that there has, in contrast, been a pronounced world cycle since 1969. The only question is the extent to which this can legitimately be attributed to the breakdown of Bretton Woods. Those of us who date the beginning of the end of Bretton Woods to the abandonment of the gold pool in March 1968, on the grounds that this transformed the reasonable symmetry of Bretton Woods' reserve constraint into the asymmetry of a dollar standard which paved the way for "benign neglect," may argue that the inflationary boom of the early 1970's can be explained that way. Doubtless the oil price increases of 1973 and 1979 were the primary causes of the ensuing global recessions, but the reason that both recessions were more severe than policymakers would have chosen *ex ante* on

grounds of anti-inflation policy can most plausibly be explained as a consequence of failure to appreciate the cumulative impact of other countries' policies (Lucio Izzo and Luigi Spaventa, 1981) and of attempts to engineer "virtuous circles."

### III. Concluding Remarks

It has often been said by supporters of present arrangements that international monetary problems derive from the policies countries pursue, not from "the system." If only each country would look after its own fundamentals, the system would look after itself. The converse of that proposition is undoubtedly true: if countries do not take due account of fundamentals, including fundamentals that produce ill effects only in the long run (if they pursue unemployment targets below the natural rate, or accumulate debt in quantities that jeopardize creditworthiness), the system is in trouble. But the proposition itself seems to be only as valid as the thesis that short-run anticyclical policies are useless. To the extent that there is a role for demand management policy to react to shocks, it is better that countries select their policies under the constraint that the (real) exchange rate not be changed except for medium-run adjustment. By imposing that constraint in the context of a system of reasonably symmetrical reserve constraints and an expectation that countries would aim for full employment, Bretton Woods contributed significantly to the stability, and therefore to the longevity, of the postwar boom. It accomplished this by influencing the policies that countries pursue: the antithesis between countries' policies and the international monetary system is a false one. To say that existing arrangements are the only ones that could have reconciled the policies pursued over the past decade is to condemn those arrangements, not to dismiss alternatives.

To recognize that the architects of Bretton Woods sought a comprehensive and enlightened policy assignment (and I cannot otherwise make sense of the wartime discussions), and that this assignment did indeed guide policy in the postwar world, is not to overlook the deep flaws in the Bretton Woods

system. One can argue that the system worked as well as it did for a little over a decade because of a series of happy accidents: liquidity was about right despite the absence of any mechanism to secure that result, exchange rates were reasonably aligned despite the attempt to suppress realignments, inflation was low, the reserve center still acted as though the suspension of gold convertibility would be a disaster. Bretton Woods did not provide mechanisms capable of maintaining such a satisfactory conjunction of circumstances. The SDR agreement was intended to provide that flexibility with regard to the quantity of reserves, but it was not complemented by those additional reforms (limited exchange rate flexibility, asset settlement) that were needed to allow the system to survive. My contention is that the neglected virtues of Bretton Woods were sufficiently real to make that failure a matter of regret.

Bretton Woods worked for a while because its rules were consistent with the needs of the time and, until emergence of the dollar overvaluation, acceptable to the dominant power. Some of its rules, such as an orientation of exchange rates to medium-run objectives, could be a useful element of any return to an organized system. In other respects it is clear that the rules would have to be very different: there is no prospect of legislating a return to effective reserve constraints. But those who are shocked by the complacency with which Washington is viewing the current dollar overvaluation must agree with the political scientists Robert Keohane and Joseph Nye (1984, p. 25), as well as Cooper (pp. 1227-28), who argued that international regimes are to be sought to protect countries not only from competitive behavior by their peers, but also from their own short-sighted follies.

## ECONOMIC EDUCATION: THE USE OF COMPUTERS<sup>†</sup>

### Computer Applications in Pre-College Economics

By JOHN M. SUMANSKY\*

Despite the fact that computer technology has become commonplace in the schools, its full impact on education in general and economics education in particular has yet to materialize. Some have been disappointed, expecting that the impact would have been felt by now. Others take the fact that the impact has not yet materialized to signify that it will never occur. Still others suggest that the true educational impact is now only beginning to unfold and may as yet not be able to be known by us. Although the temptation is great to explore these positions more fully; rather, in this paper I want to accomplish somewhat more modest objectives.

First, I will provide a sketch of the landscape of present day economics instruction in the nation's schools. Against this landscape, I will then discuss the software which is available for the teaching of economics, K-12. This discussion will lead to at least a partial explanation of the general dissatisfaction with the present generation of software available for economics instruction.

Second, I will discuss what, in my opinion, is a major obstacle limiting the ability of economics to take full advantage of the computer. My objective will be to identify action that must be taken if economics is to keep pace with other disciplines in developing effective educational uses of the computer.

#### I. The Landscape: Reality of Pre-College Economics Instruction

At the pre-college level, the microcomputer has more or less been superimposed on the existing educational landscape rather than having had a new one painted in which the computer was an integral part of its composition. To be able to judge how successful this imposition has been, we need to develop an understanding of the existing landscape by looking at several of its features.

First, in the teaching of economics at the pre-college level, one has to grapple with cognitive constraints. Early age students are less able to deal with complex ideas, abstractions, and higher-order thinking than their older counterparts. This fact constrains what and how much economics *can* be taught.

Another important feature relates to the curriculum. There is a core curriculum, namely reading, writing, and arithmetic. As presently structured, economics is not likely to be found as a separate area of study. If found, it is an integrated part of some other subject matter.

A third feature is directly related to the centrality of the textbook in pre-college instruction. What economics is taught, is overwhelmingly related to the textbook. If the text in use covers an economic topic, then teachers likely will cover it in the classroom.

A fourth feature of the K-12 education landscape has to do with the presence of the computer. Today nearly 85 percent of schools in this nation have computer capabilities and that percentage is expected to rise to 100 percent over the next few years as the price of hardware declines. The predominant hardware in use is the Apple, with TRS-80 and Commodore also in evidence. These three

<sup>†</sup>*Discussants:* Susan K. Feigenbaum, Claremont McKenna College and Claremont Graduate School; Herbert R. Fraser, H. W. Fraser Associates; F. Trenery Dolbear, Brandeis University.

\*Program Director, Joint Council on Economic Education, 2 Park Avenue, New York, NY 10016. Thanks are extended to Robert Highsmith and Michael MacDowell for helpful comments.

account for about 80–90 percent of all hardware presently in use.

Although the landscape contains a number of other dimensions, the four above features define the picture well enough for present purposes. And it is against this landscape that I offer some general observations about the software that is known and available for teaching economics at the pre-college level.

The list of known and available software for teaching economics has grown to more than 150 titles—covering economics instruction for all grade levels and ranging over a myriad of topics from coin-counting to macroeconomic simulations. The vast majority are written for use on the Apple.

The software is not distributed equally across the grade levels. More is available for use at the upper grades than at the lower grades, a fact which is consistent with the grade location of computers and with the curriculum.

At lower-grade levels, software is available to teach single, simple concepts at cognitive levels appropriate to the age level. The predominant computer applications are drill and practice and tutorial, both of which are appropriate to the teaching/learning environment in the lower grades. For example, the Joint Council on Economic Education's *Piggy Bank* (JCEE, 1984), a software package for K-3rd grade students, introduces the abstract concept of money in concrete terms, a presentation which is appropriate for 7–8 year-old students. And the learning activity is presented in a curriculum context familiar to teachers, that is, developing basic math skills such as counting.

At the high school level, software packages are available dealing with complex concepts and topics. For example, the JCEE *Marketplace* is a three-cognitive-level tutorial on price determination. The complex concept is treated abstractly using approaches which are consistent with the intellectual capacity of the high school student, textbook, and curriculum.

Experience—as evidenced by software developed to date—demonstrates that the computer can be programmed to produce learning activities fairly easily. Individuals have

been successful in developing imaginative and interesting economics activities, when judged against the landscape of pre-college economics instruction. While not all software for economics instruction have desirable characteristics, enough do that they should cause us to be optimistic about the future.

In addition to optimism arising from mild successes to date, there is another major reason for optimism about the future of computers and economics education. The structure of economic knowledge, the ability to break that knowledge down into component parts, the cumulative nature of acquisition of economic knowledge, and the ease of finding examples of ways of usefully applying economic knowledge, all have great consistency with the way in which knowledge must be structured and interpreted in order to develop computer learning activities.

Despite my fairly generous and optimistic views on the present generation of economics software, it is difficult to ignore the literature on computers in the schools which contains more than passing reference to the inadequacy of education software in general. Much the same has been heard about economics software at the K–12 level.

In my opinion, there are two main reasons for the general dissatisfaction. One reason stems from the fact that appropriate evaluation paradigms for software/computer use have yet to be developed. Especially at the grade school level, “it is difficult to test for the effectiveness of a simulation package in improving educational attainment when that package attempts to achieve goals which are difficult to achieve with a textbook, lecture or discussion” (Robert Schenk and John Silvia, 1984, p. 241). Research on the effectiveness of the microcomputer as a substitute for or complement to present teaching and learning—especially at the K–12 levels—is nonexistent! In its place is uncertainty and uncertainty breeds dissatisfaction.

Another and perhaps more fundamental dissatisfaction with present software arises from a widespread belief that “drill and practice” and “tutorials” are glorified page turners. Since observers find most K–12 software to be drill and practice and tutorial

aimed at lower cognitive levels, they naturally judge the present generation of software to be poor. I part company with those who base their judgement on this criterion because there is "...considerable evidence that intellectual skills...require considerable exercise before they become fully effective. Consequently, even though practice is a less glamorous goal for computer-based education, it is one that should be vigorously pursued" (Robert Lesgold, 1983, p. 69).

I think the criticism of and dissatisfaction with present-day educational software is serious, *but* not because drill and practice and tutorial are inherently poor uses of the computer, but rather because the dissatisfaction reflects a much more serious problem. In Section II, I will argue that a new body of research knowledge will be required to enable the discipline of economics to take full advantage of the computer.

The absence of research of the kind needed has forced software developers to rely on personal classroom experience and professional intuition to design instructional activities on the computer. Since experiences and intuition differ from one developer to the next, we tend to see rather different paths being mapped out to reach identical learning outcomes. This instructional design technique is certainly not unique to the preparation of computer materials. One need only pick up any two principles texts to see two authors differing in their views about what ideas in what sequence are prerequisite to learning a complex concept. But, unlike printed texts, a user other than developer cannot alter the program to suit his or her own "style" or approach. So, the program either is dismissed as incorrect, inappropriate, or interesting but trivial.

## II. The Computer and Economics: Potential and Path to Progress

Up until now, the more powerful applications of the computer have eluded economics and will continue to do so until research of a particular kind is conducted which will *enable* developers of economics software to produce computer activities which demand intensive intellectual participation on the part of the

student, guide students through *optimal* sequences of discrete pieces of economic knowledge accumulating to a desired learning objective, diagnose and treat errors in reasoning, and build on the unique characteristics of individual students. This is the potential of the computer, a potential which is as yet beyond the grasp of economics.

For progress to be made in designing powerful computer applications in economics, it is clear that intuition, personal observation, and the simple transformation of unique classroom lectures into computer lectures will not serve us well in the future. What is required is the filling of a research agenda which was outlined exactly thirty years ago at the Riverdale Conference. The conference issued the following call:

Economists and educators alike need to know what problems their students—of varying abilities—*are* interested in; or *can be* interested in. They need to know whether the commonly used methods for working through problems to understanding *actually* develop the knowledge and competence that are hoped for. They need to understand the learners' environment against which things to be learned are by necessity presented.

Work of a realistic, perceptive, and intelligent sort depends upon an accurate and complete knowledge of facts (what is being done, what can be done, the relationships among various factors and teaching success however defined), it seems undesirable to trust "common sense", or unsystematically acquired "experience", for its acquisition. Systematic, objective, scientific investigation—a program of research—seems definitely to be called for.

[James Gemmell et al., 1954, p. 142]

While the Riverdale Conference did not deal explicitly with computer applications, the questions raised there, in retrospect, are most relevant to the task of producing knowledge that will enable the development of more powerful economic education software. In fact, had their suggestions been followed, economics software might have had a different look today. As it stands, econom-

ics is not included among those disciplines that have a robust understanding of the role of lower cognitive skill development in leading to higher skills. For example,

In mathematics, research efforts are beginning to achieve a rapprochement between understanding and drill; in reading evidence accumulates for the dependence of the "intellectual" aspects of reading on automation of lower level skills, such as word recognition; even in domains such as radiology, the role of highly overlearned perceptual skills in the course of diagnostic reasoning is becoming important. [Lesgold, p. 69]

Because of this research, other disciplines are much more comfortable with and accepting of drill and practice and tutorial programs than economics seems to be. And their drill and practice and tutorials are quite different than anything available in economics. In short, economics does not have a literature comparable to mathematics and physics. Witness the following sample of paper titles: "Unlearning Aristotelian Physics: A Study of Knowledge Based Learning"; "Expert and Novice Performance in Solving Physics Problems"; and "Learning Without Understanding: The Effect of Tutoring Strategies on Algebra Misconceptions." A quick perusal of this list suggests that research in other disciplines has been and is being pursued to answer three important questions: is there anything "systematic" about errors students make? What are the key differences between "expert" thought/problem solving and "novice" approaches? What are the component parts (i.e., the building blocks) of the disciplines in question? These issues bear a strong resemblance to those identified at the Riverdale Conference.

It is my contention that answers to these questions are basic to the development of educational software of great value. I argue that because mathematics and physics and several other disciplines have such a literature, they also have a "different" type of software available.

In physics, for example, computer programs are available that allow students to

compare what would happen if their naive beliefs were true with what happens in a world governed by Newton's laws. This program would not be possible *unless* their research program clarified differences in novice knowledge vs. expert knowledge.

In mathematics, a programmed diagnostic system is available that determines whether deleting one or two specific steps in the subtraction process leads to the exact error pattern a child displayed. The program allows a specific conceptual problem to be more readily identified and then overcome. It is possible not only to detect missing knowledge, but also to provide hints that lead students to discover missing steps in their mathematics procedures.

This program—though far from perfect—would not have been possible without a prior research program which identified the specific steps in mathematics problem solving and systematically linked errors in math to the missing or incorrect steps.

A number of other examples could be given here. But, in general, it is likely that the absence of economic education research of the kind being done in several other disciplines will hinder the ability of the economics discipline to take full advantage of the power of the computer. Other disciplines are making rapid advances along these lines, economics is not.

### III. The Future: A Broadened Research Agenda

There are some immediate needs for research on the use of the computer in economics. There is an immediate need for answers to questions like:

1) Is the computer more effective as a substitute for or complement to alternative means of transmitting economic knowledge?

2) To what extent does drill and practice activity contribute to higher-order learning in economics?

3) What are the optimal classroom environments and educational inputs for using the computer in teaching economics?

A longer-term research program needs to begin to identify how economic knowledge can be broken down into its component parts and how the parts are to be assembled in

sequences leading to specific learning outcomes. Prerequisite knowledge, including the experience and intellectual maturity of students at various age levels, needs to be addressed against the backdrop of the cognitive processes of information accumulation, information processing, and information utilization. Each of these cognitive processes needs substantial research to uncover its marginal contribution to "expert" economic knowledge levels in economics.

For example, with the process of information accumulation, just what role do personal experiences play, how important to higher-order thinking are personal experiences, and how important to higher-order thinking is knowledge of the definitions of key economics concepts?

Research needs to be done on information processing—that is, what cognitive processes or problem-solving models do students use to sift through economic information?

We need to determine not only which ideas and concepts are prerequisite to higher-order thinking in economics, but also how one goes about recognizing them when they are not known by novices, and how one knows when to reach out and draw in another concept and how to link them together in a sequence to be able to deal with economics problems/issues of high complexity.

Finally, differences between "experts" and "novices" in the ways in which economic information is accumulated, processed, and utilized needs to be studied. Perhaps this is the most crucial item on the research agenda.

This is an imposing research agenda, yet an important one if we are to truly realize the potential of the computer. And, while it is the quest for realizing the educational potential of the computer which heightened the urgency of this research, the computer also appears to be a possible solution to some of the questions raised. The computer appears to have great power as a research tool—because it offers researchers a way of presenting alternative economic learning se-

quences without being tainted by instructor differences.

Experiments using alternative sequences can be devised to measure the differences in learning outcomes for students with different backgrounds, experiences, intellectual maturity, prior knowledge, and learning styles. The ability to replicate such studies is also enhanced.

Thus, intuition and experience no longer need be the only information used to decide which knowledge sequence is best for teaching a particular economic concept. Armed with this new knowledge, "smart" programs can be written to diagnose student readiness for economics learning, select the best sequence of ideas, and present the student with virtually an unlimited array of remedial work and application problems relevant to the student's characteristics.

# Macro Simulations for PCs in the Classroom

By KARL E. CASE AND RAY C. FAIR\*

There has always been a large difference between macroeconomics in the classroom and macroeconomics as it is used in practice. Macroeconomics of the classroom is basically theoretical, and it is taught almost exclusively in a simple comparative statics framework. Practicing macroeconomists, on the other hand, work with time-series data, sophisticated statistical techniques, and large-scale macroeconometric models. The PC revolution has now made it possible to bring macroeconometric models into the classroom.

The model in Fair (1984), which consists of 128 equations, has been programmed to run on a PC; this paper will discuss its potential for use as a teaching tool at the elementary and advanced levels. The experience so far has been quite encouraging.

## I. Hardware Requirements

The software was written with the aim of minimizing the amount of memory needed to run the program. This amount turned out to be 128K, which includes the memory needed for the operating system of the computer. Although the model is fairly large (238 endogenous and exogenous variables), only five quarters' worth of data are needed in core memory at any one time. Data for five quarters are needed because the model has lagged values of up to four quarters. After the model is solved for a given quarter (the fifth quarter in memory), the results for that quarter are written to the disk, a new quarter's worth of data are read (with the old first-quarter's data dropped from memory),

and the model is solved for the new quarter. This process is repeated throughout the prediction period. Because of this structure, the program does a fair amount of reading from and writing to the disk.

The program runs on IBM and IBM-compatible personal computers; it also runs on the DEC Rainbow and the Wang. It can be used on computers with only one disk drive, although two disk drives are more convenient. A version of the software allows one to use Lotus 123 to analyze the output; for this version the memory requirement is 192K. It takes about 10 to 20 seconds on a standard IBM PC to solve the model for one quarter. A twelve-quarter solution thus takes about 2 to 4 minutes.

## II. The Software

The software is menu driven and is easy to use even for students who have no prior experience using PCs. One of the main things that users must learn is the treatment of data sets. Included with the software is a "base" data set. This data set contains data on the endogenous and exogenous variables for the period of interest and all the other information, such as the coefficient estimates, that are needed to solve the model. For many applications the period of interest is an actual forecast period, for example, 1984:4 to 1987:4. In this case the values of the endogenous variables in the base data set are predicted values. If the period of interest is some historical period, the values of the endogenous variables in the base data set are the actual values. The teacher or student can use the "historical" part of the software to create a base data set for any six-year period from 1952 on.

Assume that the base data set is for an actual forecast period, so that the endogenous variable values are predicted values. This means that if a forecast is run with no changes made to the base data set, the pre-

\* Wellesley College, Wellesley, MA 02181, and Cowles Foundation, Yale University, New Haven, CT 06520, respectively. The software discussed herein is marketed under the name of FAIRMODEL by Economica, 2067 Massachusetts Avenue, Cambridge, MA 02140. The accompanying workbook is by Anthony Blackburn and Case (1985).

dicted values of the endogenous variables will simply be the values already in the data set. The job of the student is to change some of the information in the base data set and run a new forecast. The main menu that the user faces is as follows:

Enter	To
1	Change assumptions about monetary policy.
2	Change exogenous federal government fiscal policy variables.
3	Change exogenous state and local government variables.
4	Change exogenous foreign sector variables.
5	Change other exogenous variables.
6	Change equations by the use of add factors.
7	Drop or add equations.
8	Take equations to begin after the beginning of the forecast period.
9	Change coefficient values.
10	Exit.

The monetary and fiscal policy options (1 and 2) are the ones most often used. These are discussed in Sections III and IV below. Options 3, 4, and 5 allow other exogenous variables to be changed. Option 6 allows add factors to be used, something which is not of much interest for teaching purposes. Option 7 allows equations to be dropped, which means that the equations are not used and the endogenous variables that are explained by the equations are taken to be exogenous. This option is sometimes useful for examining subsets of the model's equations. Option 8 allows the equations to be dropped for only part of the forecast period. Finally, option 9 allows the coefficient values to be changed. An example of the use of this option is presented in Section III.

Once the changes have been made, a new forecast is run. New data are created from this run, which consist of the user's changes from the base data set and the new predicted values. The student can then use the software to examine the differences between the predicted values in the two data sets. These differences are the effects that the changes

have had on the endogenous variables in the model. As many new data sets can be made as the user likes, any previously created data set can be used as a base data set, and any two previously created data sets can be compared. The fact that all the information about an experiment is contained in one data set makes it very easy to compare alternative runs.

If the period of interest is historical (any period except the current forecast period), then the endogenous variable values in the base data set are the actual values, and a new "base" data set must be created before any changes are made. This data set is created by simply solving the model over the period of interest with no changes made. The endogenous variable values in this data set are then predicted by the model and are the appropriate ones from which to make comparisons when changes are made in running experiments. If the changes were made from the original base data set, the differences between the endogenous variable values in the new and base data sets would have included the predictive errors, which are not, of course, a result of the user's changes.

### III. Intermediate and Advanced Teaching

Knowledge of the structure of the model is needed for intermediate and advanced teaching. The theory behind the model is that agents make decisions by solving multiperiod optimization problems. The key decision variables for households are consumption and leisure, and the key decision variables for firms are prices, wages, production, investment, and employment demand. A typical estimated equation in the model has a decision variable on the left-hand side and variables that are assumed to affect the decision on the right-hand side.

The first step in teaching with the model is simply to go through the 30 estimated equations. There are 9 estimated equations for the household sector: three categories of consumption (service, nondurable, and durable), housing investment, four categories of labor supply (labor force participation of males 25-54, females 25-54, and all others, and the number of people holding two jobs), and

a demand for money equation. There are 12 equations for the firm sector. The 7 most important explain the firm sector's price level, production, investment, demand for workers, demand for hours per worker, the wage rate, and the demand for money. The other 5 equations explain overtime hours, dividends, interest, inventory valuation adjustment, and depreciation. The explanatory variables in the main equations are consistent with the view that households maximize utility and firms maximize profits. The equations are fairly easy to explain since one can appeal to students' knowledge of microeconomics.

The short-term interest rate in the model is explained by an interest rate reaction function of the Federal Reserve, and this is a good equation to discuss next. It is a "leaning against the wind" equation in the sense that the Fed is estimated to allow the short-term interest rate to rise as 1) inflation rises, 2) labor markets get tighter, 3) real output growth increases, and 4) lagged growth of the money supply increases. The inclusion of this equation in the model means that monetary policy is endogenous.

The remaining 8 estimated equations in the model include two term structure equations (explaining a long-term bond rate and a mortgage rate), a stock price equation, a demand for currency equation, an equation explaining bank borrowing from the Fed, a demand for imports equation, an equation explaining unemployment insurance benefits, and an equation explaining the interest payments of the federal government.

The next task is to review the 98 identities. A key feature of the model is that all flow-of-funds and balance-sheet constraints are met, and many of the identities relate to these constraints. There are six sectors in the model (household, firm, financial, foreign, state and local government, and federal government), and for each sector there is an identity determining its level of savings. The sum of savings across sectors is zero, since the revenue of one sector is the expense of some other sector or sectors. There is also an identity for each sector that relates the level of savings of the sector to changes in its assets and liabilities: any nonzero value of savings in a period must result in the change

in at least one asset or liability. Explaining these identities carefully for one sector allows one to go through them quickly for the other sectors. The remaining identities in the model, which are equations like the *GNP* definition, can also be quickly reviewed.

One is now in a position to have the students run some experiments. A good starting point is to have the change be an increase in federal government purchases of goods, which is a standard expansionary fiscal-policy action. This change can be analyzed under four different assumptions about monetary policy. In other words, four solutions of the model can be made for the fiscal-policy change, each solution corresponding to a different assumption about monetary policy. The four assumptions are: 1) the interest rate reaction function used (monetary policy endogenous), 2) the short-term interest rate unchanged from the base case, 3) the money supply unchanged from the base case, and 4) nonborrowed reserves unchanged from the base case.

Having the students explain carefully the reasons for the differences across the monetary-policy assumptions is an effective way of having them learn about the links between monetary policy and fiscal policy. Under each of the assumptions, the amount of government securities outstanding (the open market operations variable of the Fed) is endogenous, and the students should be required to explain why the government securities variable changed in the particular way that it did for each run. An example of a difference between runs is that the economy is more expansionary under the assumption of an unchanged interest rate than it is under the use of the interest rate reaction function. With the interest rate reaction function, the Fed responds to the fiscal-policy action by allowing interest rates to rise, which slows the expansion. The increase in government securities outstanding is larger in this case.

Explaining the four cases generally takes two or three class periods. There are two types of things to be learned from these results. One is the response of the household and firm sectors to the fiscal-policy change, and the other is the relationship between monetary policy and fiscal policy. The results

for the household and firm sectors can be related to the prior discussion of the individual equations for these sectors. The model has the feature that both an expansionary fiscal policy and an expansionary monetary policy stimulate private demand, and so to some extent one can consider the question of the relationship between monetary policy and fiscal policy without knowing too much about the detailed responses of the household and firm sectors. This makes the results somewhat less model specific than one might otherwise think. Also, accounting for the flow-of-funds and balance-sheet constraints is not model specific in the sense that these are just identities, and so anything that is learned from this accounting framework is not model specific. For example, crowding out issues can be easily examined since any deficit that the government runs from an expansionary fiscal-policy action must be financed by an increase in savings of at least one other sector, and the model tells one directly which sectors are doing the increased saving.

The next step is to run other fiscal-policy experiments. Various tax rates can be changed, the level of transfer payments can be changed, and the number of government jobs can be changed. These runs allow the effects of different fiscal policies to be compared (given the same monetary-policy assumption for each experiment). For example, a decrease in the personal income tax rate increases labor force participation in the model (a positive labor supply response), which, other things being equal, leads to a rise in the unemployment rate. The relationship between output changes and unemployment rate changes is thus different for this experiment than it is for the experiment in which government spending on goods is increased, where there is no direct labor supply response.

Pure monetary-policy experiments can also be run. The short-term interest rate, the money supply, or the level of nonborrowed reserves can be made exogenous and changed.

An example of an interesting advanced experiment is the following. First, run a particular experiment and record the results. Second, change the coefficients in the demand for money equations to alter the inter-

est sensitivity of the demand for money. Then run the same experiment for the different coefficient values, record the effects, and explain the differences. (This experiment will require a different base run because of the different coefficients used.)

Many other exogenous variables in the model can be changed. One of considerable current attention is the price of imports. An increase in this variable generally has the effect of increasing domestic inflation and decreasing real output. This negative correlation between inflation and output is contrary to the positive correlation that generally results when demand is stimulated by monetary or fiscal policy. These different correlations show the student that there is no simple relationship between inflation and output in the economy.

After a few weeks of going through results, students begin to understand simultaneous effects. They can think through a rather complicated series of variables affecting one another. They also learn that most changes take time to work themselves out in the economy.

As a final note, we have found that students often think of interesting experiments. One example is the following. The two term structure equations in the model are not consistent with the expectations theory of the term structure if expectations of the short-term interest rate are rational in the Muth sense. In other words, the model does not have rational expectations in the bond market. One student, however, forced the model to have this feature by dropping the two estimated term structure equations and adjusting the long-term rates to be consistent with the model's future predictions of the short-term rate. This was done by solving the model many times, each solution corresponding to a particular set of values of the long term rates, until, given the model's predictions of the short-term rate, the consistency requirement was met.

#### IV. Elementary Teaching

Elementary students are introduced to the basic concepts of macroeconomics through simple comparative static models. Textbooks begin with an explanation of "equilibrium

national income determination." The simple aggregate supply/demand equilibrium model continues to be a very useful pedagogical tool. It provides a basic structure within which theoretical debates and policy options can be discussed. Although many concepts and alternative theories can be incorporated into this structure (for example, theories of consumption/savings behavior), there are a number of problems that result from its use.

One problem is that students often come away from principles courses with a very inaccurate impression of time lags and of the magnitude of potential policy impacts. Shifting the aggregate demand curve in a static model, for example, will reveal the direction that most variables will move, but not the magnitude or timing of the movements. Good students in principles courses will be able to tell you that a personal tax cut is likely to increase disposable income, initially increase both savings and consumption, and ultimately raise the "equilibrium level of *GNP*" by a multiple of the original tax cut. What they cannot tell you is how long it takes to get to the new "equilibrium," or how large the ultimate change in *GNP* is likely to be.

In teaching the multiplier we speak of "periods" (as smaller and smaller disequilibria lead to the new equilibrium), but the periods are used only to teach the character of the adjustment process and they are never tied to actual intervals of time. The multiplier values that students think exist in the real world are usually not sensible. It is not uncommon for even good students to think that the multiplier is greater than five "since the marginal propensity to save is less than .2."

The use of the software for the Fair model provides a useful way of teaching students about the adjustment process and about the likely size of the policy effects. The model can be used for this purpose without having to teach the detailed specification of the model. For example, students can simply take the base forecast for some period, increase real government purchases of goods by one billion dollars, and observe and plot the resulting changes in real *GNP* over the period. This can be done under the various assumptions about monetary policy, and by running these experiments the students can

get a good idea of both the size of the policy effects over time and the influence of monetary policy on fiscal policy.

Another important use of the software at the elementary level is examination of the historical data. Elementary students receive only a cursory exposure to the empirical side of macroeconomics and recent economic history. If data are discussed at all, they are presented in simple tables. Elementary texts do contain descriptions of recent events, but students "hands on" learning is generally accomplished by working through exercise sets built around simple hypothetical economies ("the king decides to stimulate demand with a tax cut of 10").

Experiments with the Fair model use real data and can be constructed around actual historical events. To prepare for the experiments, it is useful to have students do a series of descriptive exercises with the quarterly macroeconomic data. Over the last fourteen years, when was the unemployment rate the highest? What happened to real *GNP* over the same period? Explain the relationship between real and nominal *GNP*. How much did real *GNP* per capita grow between 1960 and 1970? Between 1970 and 1980? Describe the behavior of the money supply between 1970 and 1975.

Once the students have some familiarity with the data, the simulation experiments can begin. The workbook that accompanies the software contains 49 experiments. Most experiments begin with a newspaper or magazine article describing some event, controversy, or historical period. For example, last year there was a widely publicized debate between Martin Feldstein and Donald Regan about whether the Fed should hold the line at 6 percent money growth or move to an 8 percent target. The model can be used to simulate these two policies, and students can compare the results. Which yields higher interest rates? Is there an impact on nominal *GNP*? On real *GNP*? Explain the links. What happens to projected inflation under the two policies?

Another experiment is more historical. President Ford asked for and got a substantial tax cut in the spring of 1975 (newspaper article). At the same time the Fed was pursuing an easy monetary policy (look at *M1*

growth and interest rates). Both policies were in response to the recession that hit bottom in May of 1975 (verify). A modest "recovery" began in the second half of 1975 (what is meant by recovery?). Now go back to 1975 and do away with the tax cuts. What would have happened? Now restore the tax cuts, but hold money growth to 4 percent. Who was more responsible for the recovery, Arthur Burns or Gerald Ford, or is this question meaningful?

Other experiments include an examination of the effects of policy changes on labor supply and investment. In 1981 Robert Eisner did a major project for the Office of Tax Analysis at the Treasury Department in which he simulated the corporate tax cuts of the 1981 Economic Recovery Tax Act using

several large econometric models (DRI, Chase, etc.). Nearly identical experiments were run by 37 undergraduate Public Finance students at Wellesley College who analyzed the supply-side impacts of smaller and larger tax cuts.

# Cost Effectiveness of Computer-Assisted Economics Instruction

By DARRELL R. LEWIS, BRUCE R. DALGAARD, AND CAROL M. BOYER\*

Is computer-assisted instruction (CAI) in economics cost effective? The early enthusiasm and verified instructional effectiveness of CAI during the 1960's and early 1970's led many to believe that CAI adaptations would increase into the 1980's. Although CAI was especially visible in the teaching of college-level economics, a recent review of the literature indicates that the use of CAI in economic education appears to have peaked during the early to mid-1970's (Dalgaard et al., 1984). The decline that followed is often attributed to questions of the cost feasibility and cost effectiveness of CAI in both economic education (John Soper, 1974) and in education generally (Robert Butman, 1973; Denyse Forman, 1982; and Greg Kearsley, 1977). In light of recent advances in computer technology and recent marketing innovations in the development, dissemination, and use of mini and micro computers (including concurrent cost reductions), many of the previously discontinued CAI activities may now be both cost feasible and cost effective, and should therefore be reconsidered.

Unfortunately, however, systematic efforts to collect data on the costs of CAI are seriously lacking. Those few studies that do report cost data do so only for mainframe-type CAI systems that, for the most part, are now at least five to ten years out of date. Clearly what is needed today is not only more current, carefully designed cost information, but also systematic assessments of the cost feasibility and cost effectiveness of both existing and new CAI systems.

## I. Is CAI Effective?

Within the field of economic education, surprisingly little is known about the effectiveness of CAI. For example, virtually nothing has been reported in the literature on the use of CAI in elementary and secondary schools. Although one could generalize from studies that focus on other subject matter areas, additional studies clearly are needed in economic education at these pre-college levels of instruction.

Even at the college level, only a few studies have systematically examined the effectiveness of CAI in economic education. Of the twenty-one studies of college-level CAI reviewed by Soper, for example, only six had included any empirically based assessment of student performance (i.e., achievement and attitudes); fewer still had made any reference to costs. A more recent review by John Siegfried and Rendigs Fels (1979) focused on seven experiments that had assessed college-level CAI in terms of its impact on cognitive achievement, student attitudes, retention, and the distribution of benefits between high- and low-achieving students. All seven reported positively on the effectiveness of CAI. Only two other carefully designed studies of the effectiveness of CAI in economics are reported in the literature (Donald Paden and Michael Barr, 1980; James Marlin and James Niss, 1982).

Unlike the recent literature in economic education, the education research literature has shown a consistent interest and involvement in CAI at all levels of instruction. Other reviewers generally support the effectiveness of CAI and usually conclude that it is effective in improving student achievement. At the elementary school level, for example, a number of extensive reviews (see especially Forman; Dean Jamison et al.,

\*Professor, Associate Professor, and Research Specialist, respectively, University of Minnesota, Minneapolis, MN 55455-0211.

1976; James Kulik et al., 1983) all reported results from a large number of independent studies showing substantial instructional advantages for CAI. Although it has proven more difficult to show the achievement advantage of CAI at higher levels of instruction, these same reviewers generally concluded that CAI was at least as effective as conventional instruction at the secondary and college levels.

Perhaps the most important and consistent finding in the education research literature concerning the effectiveness of CAI is its effect on instructional time. Although seldom addressed in most studies, whenever instructional time has been examined, CAI has been found to have profound effects in reducing instructional time for students. In studies from both school and industry settings, CAI has been reported as saving anywhere from 30 to 90 percent of student learning time (Butman; Kulik et al., 1983). Paden and Barr, for example, reported that CAI students not only performed better in economics than non-CAI students, but that they also spent less time studying than their non-CAI peers.

When student attitudes toward the subject matter and the quality of instruction are assessed, they are generally favorable with respect to CAI (in economic education, see especially Bernard Booms and D. Lynne Kaltreider, 1974; Paden and Barr). Other reviewers also have found that the effect of CAI is even stronger and more positive on student attitudes toward computers than on attitudes toward the subject matter and the quality of instruction.

In addition to the positive effects that CAI reportedly has on student achievement, attitudes, and instructional time, the research literature reveals several other advantages for CAI, including its capability for individualizing the instruction process; for keeping students informed of their progress through immediate feedback and achievement summaries; for simulating experiences not possible without a computer; and for allowing students to review previous instruction, request special help, or continue on to extra learning activities (in economic education,

see especially Allen Kelley, 1972; William Davisson and Frank Bonello, 1976).

## II. Is CAI Economical?

If the above generalizations are valid, then one should expect the use of CAI in some instructional settings to contribute to enhanced efficiency. At the least, in assessing alternative methods of instruction, one must examine all of the likely costs and outcomes. Clearly, it is necessary to establish a basis for comparing CAI with alternative methods of instruction in terms of costs and outcomes before any assessment can be made of the alleged efficiency or cost effectiveness of CAI. Most importantly, even when no significant differences in student achievement are realized from the introduction of CAI into an instructional setting, one should expect to realize (and measure) changes both in *student-teacher ratios* and *student instructional time*.

To illustrate, consider the following example. Assume an instructional setting where students with CAI score about the same as students with conventional instruction. Classroom instructor costs are assumed to be \$1.40 per student hour. With CAI, however, we note that each instructor can manage (i.e., teach) twice as many students. Consequently, instructor costs per student hour can be reduced by one-half or \$0.70. Add \$1.50 for the terminal-hour cost of a CAI system (computed as the average total cost per hour) and \$3.60 per hour for student time (opportunity cost for lost wages) for a total cost of \$5.80 per student hour on the computer system. Average time-improvement factors for CAI of 0.7 are not unreasonable (Butman), so final total cost per equivalent classroom hour is about \$4.00. This might compare with a cost of \$1.40 per hour for the instructor plus \$3.60 for student time or \$5.00 total for conventional instruction. Given the above assumptions, a cost savings of approximately \$1.00 per hour is forecast for CAI in this illustration. In other words, CAI is 20 percent more efficient than conventional instruction.

As a real example, when Deltak, Inc. (1981)

compared its industrial training programs and considered the cost of student time, it found that a five-day, instructor-led course of 10 students was more costly than a computer-enhanced, learner-paced, multimedia approach at a ratio of \$1,120 to \$680. In short, in this example, conventional classroom training was 65 percent more expensive than CAI.

Computer-assisted instruction can contribute to instructional efficiency (and can be more cost effective than conventional instruction) *provided* certain instructional outcomes are realized. In simplest form, CAI can be cost effective if (a) it costs the same as conventional instruction but contributes more to student achievement in the same amount of instructional time, or (b) it costs less or results in less training/instructional time for students to achieve the same learning outcomes as conventional instruction, and/or (c) it results in an increase in student-teacher ratios (which can be translated into lower overall costs to the system).<sup>1</sup>

### III. Cost Analysis of CAI

It should be clear from the above discussion that one needs cost information in order to make fully rational decisions about CAI. Unfortunately, very little hard data are reported in the literature. Often what information does exist has limited application. For example, almost all of the early investigations of cost factors related to the use of CAI explored only their cost feasibility. Specifically, these studies accumulated cost data related only to the acquisition, implementation, and maintenance of CAI. It is important to note that cost-feasibility questions do not consider student performance (i.e., achievement and attitudes) relative to the

costs of alternative methods of instruction. Costs may be compared but not with student performance in mind. Moreover, studies that do address the cost feasibility of CAI are really addressing budgetary costs and not economic costs.

Cost-effectiveness studies, on the other hand, consider some objective measure of student performance in alternative instructional settings, with the cost of delivering instruction as the determinant. Almost all of the studies identified in the previous section related only to some measurement of the effectiveness of CAI as compared to conventional instruction. Very few studies reported cost data in any form. Although a few cost-feasibility studies of CAI are emerging in the literature, cost-effectiveness studies of CAI are still noticeable by their absence.<sup>2</sup>

There is some precedent for the application of cost-effectiveness analysis to instructional delivery systems. Martin Carnoy (1976) and J. Mayo et al. (1975), for example, analyzed the economic costs and benefits of educational television; and K. Lumsden and C. Ritchie (1975) attempted to analyze the cost effectiveness of educational technology in a university setting. Few studies, however, have examined issues relating to costs or cost effectiveness of CAI. To illustrate, we can find virtually nothing on costs in the 59 studies of college-level CAI evaluations that were examined by Kulik et al. (1980). The 59 studies reported only on student achievement, the correlation between student aptitude and achievement, course-completion rates, student attitudes, and instructional time. A meta-analysis by Kulik and his colleagues indicated that 54 of the 59 studies reported on student achievement whereas only 8 of the 59 studies reported on instructional time. The latter is the *only* variable in

<sup>1</sup>Unfortunately, most of the current use of CAI has been in the form of additions to conventional instruction and thus precludes realizing many of these cost savings. This has undoubtedly resulted from the reality that most school and classroom settings do not permit the instructional and curricular flexibility necessary to substitute capital (in the form of new technology such as CAI) for labor in the teaching/learning process.

<sup>2</sup>This paper is a partial product of a larger project wherein we are developing a more formalized cost function with parametric estimations derived from field-based cost data on the use of CAI with micro computers in the public schools. We expect to relate such cost information to various forms of outcome data in order to estimate cost effectiveness for alternative instructional settings.

most of the reported studies that might allow for any cost analysis. In a subsequent study by Kulik et al. (1983), a meta-analysis of 51 studies on CAI at the secondary level yielded similar results. Again, no mention was made of the costs of CAI except in two studies that reported only on instructional time.

It is both surprising and disappointing to note that out of literally hundreds of citations in the education research literature on CAI, only six studies have reported any systematic examination of the empirical basis of costs (Fred Hofstetter, 1983; Jamison et al., 1970; Jamison et al. 1976; Kearsley; Henry Levin and Louis Woo, 1981; Paden and Barr). Moreover, only the studies by Jamison et al. (1970) and Paden and Barr systematically compared CAI costs in terms of value-added in student achievement with those of conventional instruction and reported on the relative success and cost effectiveness of CAI. An earlier study by Kelley did report in summary terms on the perceived cost effectiveness of TIPS (Teaching Information Processing System) in economic education, but unfortunately no empirically based cost data were presented or analyzed.

In summary, few studies in the education literature address the cost factors associated with CAI, even fewer systematically consider student instructional time and the cost effectiveness of CAI, and none addresses the cost factors associated with the use of micro computers in CAI.

#### IV. Future Directions for CAI

A recent national survey by Jack Chambers and Alfred Bork (1980) assessed the current and projected use of the computer in U.S. public secondary and elementary schools, with special emphasis on the use of new micro CAI systems. The results showed that 74 percent of all districts responding to their survey used the computer to support their instructional process and 54 percent used CAI. Furthermore, 75 percent of the districts indicated that their teachers were interested in developing new CAI programs. Chambers and Bork concluded that in the next decade, "cost reductions due to mass production and consumption for home enter-

tainment and learning will permit cost-effective uses of computer-assisted learning in both the traditional classroom and in other settings" (p. 5).

Given these current and projected activities for CAI and the micro computer in the U.S. public elementary and secondary schools, why has so little been reported, especially in the recent research literature in economic education? We believe the answer lies both in the research literature and in a number of institutional circumstances within higher education.

First, it is important to note that until recently almost all software and program developments for CAI have taken place in the offices of university faculty. Moreover, and again until only recently, most faculty were familiar and worked almost exclusively on mainframe, research-type computer systems. At the same time, the central computer facilities of most universities were expensive, perceived as fixed costs in the short run, and selected and purchased for their research capabilities. Consequently, both faculty and central administrators have had strong incentives to preserve the functional form of existing computer systems. Therefore, many universities have been more than willing to provide departments with CAI services for only their marginal costs, and often even free, simply because such provision of service provides additional rationale for use by central administration with regents and legislators for the preservation, or even expansion, of their present computer systems.

Second, given this focus on mainframe computer systems, it appears that by the mid-1970's many users of CAI—at least in college-level economics—were becoming disillusioned about its likely cost effectiveness (Soper). As evidenced by the lack of attention to CAI in the economic education literature, its rate of use even at the college level appears to have dropped off appreciably. It also is important to note that in many cases when external grants and departmental subsidies were withdrawn (as, for example, in the cases of two rather large-scale CAI projects in economics at Illinois and Wisconsin), the projects were often similarly terminated or drastically reduced. The realities of equip-

ment and on-line costs in the mid-1970's apparently dictated a lack of cost effectiveness for CAI at the college level. Even today, after ten years and millions of dollars spent on development and marketing costs by Control Data Corporation, only seven universities in the United States have adopted some form of the PLATO mainframe system for teaching economics. At least in the past, the major reason that many such projects were considered not to be cost effective was that the hardware and delivery systems were so expensive. Although there were undoubtedly other cost savings (such as trading capital for labor, freeing instructional staff for other educational services, and saving student instructional time), the perceived costs of CAI technology apparently precluded university-funded continuation of the projects at that time.

In short, the biases and fixed costs within higher education have precluded much flexibility, many resources, and much attention to the use of micro computers in CAI. Moreover, little in the literature concerning the costs of CAI has been either reported or persuasive.<sup>3</sup> At the same time, however, the public schools have had few such hindrances or disincentives, and the private companies have been actively pursuing these targets of opportunity.

As discussed above, the research literature dealing with CAI does provide evidence that CAI can be effective in the teaching/learning process within some instructional settings. Nonetheless, the fundamental question remains, is CAI *currently* cost effective?

The literature, at best, only gives us very limited information on this critical question. For most of the reported uses of CAI and at

all levels of instruction, we still do not know the answer to the question of whether CAI is cost effective. Our review of CAI cost analysis and evaluation studies in both economic education and education generally indicates that, at least at the college level through the mid-1970's when almost all CAI was on mainframe type systems, CAI probably was *not* cost effective. On the other hand, with the current costs of computer hardware less than 20 percent of what they were only seven years ago, and with the costs of such hardware and communication systems making up approximately 50 to 90 percent of the total costs for CAI (Dalgard et al.), it is safe to assume that the current costs of using micro computers are probably *less than 30 to 60 percent* of the total costs at the time the earlier studies were conducted. It also is safe to assume that any reduction in the costs of technology has been accompanied by increases in labor costs. Together, these factors make CAI a strong candidate today for reexamination and possible adoption at all levels of instruction. In short, CAI may have become both cost feasible *and* cost effective!

<sup>3</sup>It is important to note that, in addition to the lack of cost information on the new micro computer technology, a second factor limiting the implementation of CAI via micro computers is likely to be the unavailability of inexpensive software. In this regard, a number of commercial companies are rapidly developing such software, especially for use in the elementary and secondary schools. The Joint Council on Economic Education (1984), through its recent National Computer Economic Education Program, also is targeting CAI as an area of needed curriculum development and is currently supporting software development efforts.

# THE DEREGULATION OF BANKING IN THE UNITED STATES<sup>†</sup>

## Legislative Construction of the Monetary Control Act of 1980

By RICHARD H. TIMBERLAKE, JR.\*

[The Monetary Control Act] is one of the most complex and least understood pieces of legislation that I have ever seen come before a legislative body. It has been referred to as everything from a Christmas tree to a forest primeval, the latter probably being the more appropriate phrase.

U.S. Senator Donald Stewart,  
*Congressional Record*,  
March 27, 1980, p. 6910

The Depository Institutions Deregulation and Monetary Control Act (DIDMCA) of 1980 was hailed by Senator William Proxmire, one of its sponsors in the U.S. Senate, as the "most significant banking legislation since [the passage of the Federal Reserve Act in] 1913." Title I in the bill extended the Federal Reserve's control over reserves to all depository institutions and added some other powers as well. Title II called for the phasing out of all government-imposed interest rate ceilings on banks and other financial institutions and generally removed competitive inequities between them. The Act has in total eight Titles, which deal with Truth in Lending Simplification, State Usury Laws, Amendments to the National Banking Laws, and other matters. The first two Titles, however, contain the important substance of the Act as well as its contradictory implications: The power of the Fed and its regulatory scope are greatly extended. At the same time, restrictions on freedom of economic activity

for the rest of the banking and financial system are significantly relaxed.

Economists and bankers have concurred with Senator Proxmire on the importance of the DIDMCA of 1980. They have long recognized the desirability of regulatory simplification, such as homogeneous reserve requirements for banks and abolition of interest rate ceilings on time deposits, so they have applauded the deregulatory aspects of the Act. They have been remiss, however, in failing to point out the disparate treatment of institutions implied by the two major "Titles," and especially the significance of the additional powers granted the Fed.

The debates on the bill in both Houses of Congress reveal the procedure by which these two dissimilar provisions were incorporated into the same law. Fundamental to this result were the opinions and testimony of Federal Reserve Board spokesmen who significantly influenced congressional committees and were thereby instrumental in gaining additional powers for the Fed.

### I. The Ancestry of the DIDMCA of 1980

The Monetary Control Act of 1980 began in 1979 in the House of Representatives as the Consumer Checking Equity Act of 1979 (H.R. 3864) and the Monetary Control Act of 1979 (H.R. 7). Also proposed earlier were three different Senate bills: S. 85 would have made membership in the Federal Reserve System mandatory for all depository institutions, S. 353 would have had the Fed pay market interest rates on the reserve account balances of Federal Reserve member banks, and S. 1347, another Monetary Control Act of 1979. H.R. 7 was the only one of these earlier bills to pass either House before the final bill. It passed the House of Representatives in 1979, but its counterpart in the

<sup>†</sup>*Discussants:* William Beranek, University of Georgia; Richard K. Vedder, Ohio University.

Comments by William Beranek, Alfred Bornemann, George Selgin, and Richard Vedder were very helpful.

Senate, S. 1347, was not debated. All of these earlier bills served as "ancestors" for the bill, H.R. 4986, that finally passed both Houses in 1980.

## II. The "Problem" of Fed Membership

Hearings and deliberations on these various House and Senate bills began in early 1979. On February 26 of that year, G. William Miller, who was then Chairman of the Fed's Board of Governors, commented at length before the Senate Committee on Banking, Housing and Urban Affairs on both S. 85, the "Proxmire bill," and S. 353, the "Tower bill."

The first issue Miller addressed was the attrition of Fed membership. Banks had been steadily leaving the Federal Reserve for over 25 years; between 1970 and 1978, the decline numbered about 300 banks (out of about 14,500). The decline in membership was accompanied by a reduction in the proportion of members' deposits to total bank deposits from 81 to 72 percent. The explanation for this decline was seen to be the high interest rates caused by inflation. Fed member banks were required to keep zero-interest reserve balances with the Fed Banks of their districts. They also were entitled to certain services; such as the clearing of checks and access to the discount window. As nominal interest rates rose behind inflation during the 1970's, these zero-return reserve accounts became more burdensome. The new freedom achieved by nonbank financial institutions that allowed them to create quasi-demand deposits and to pay interest on them required a similar allowance for banks so that the latter could stay competitive in the struggle to get and keep depositors (Miller, p. 230).

All Fed officials, who subsequently testified on the various bills Congress considered, emphasized this "problem." Their argument was that loss of membership also meant a loss of Federal Reserve control over the banking system. "All the legislative proposals" Paul Volcker stated in his testimony, "need to be judged first of all against the central objective: We need to strengthen our ability to implement monetary policy in a variety of possible circumstances..." (1979, p. 823).

The bills, H.R. 7 and S. 85, he noted, would be accompanied by substantial reduction in "reserve balances that would be held in Federal Reserve Banks. These balances," he asserted, "*and only these balances*, provide the 'fulcrum' for the efficient conduct of monetary policy" (1979, p. 825). Volcker's views were echoed a few months later in the House by Henry Reuss of Wisconsin, who stated: "What this bill does...is give the monetary authorities a power they desperately need [sic] if they are going to pursue [an anti-inflationary policy]... Unless they have a 'fulcrum,'... a reserve base upon which they can conduct their open market policy, they are incapable of regulating the money supply" (CR, 125, 1979, pt. 15, p. 19689).

The Fed's line of argument is open to the criticism of an invalid premise—the implication that Federal Reserve monetary control depends critically on member bank reserve accounts in Fed Banks. Left out of this accounting are the banks' holdings of vault cash—Federal Reserve notes—that increased from \$7 billion in December 1970 to \$17 billion by the end of 1978. These notes are also legal reserves. They, too, are supplied by the Federal Reserve System in the same manner as reserve accounts, and are held by both member and nonmember banks and by all other financial institutions.

These two items together compose the major elements of the monetary base, the total of which is under Fed control on a day-by-day basis no matter what the values are of each constituent part. As the base is changed by Fed policies, so are changed in varying degrees the components of the conventional money stocks,  $M_1$  and  $M_2$ . Furthermore, Fed authorities know accurately the quantity of Federal Reserve notes outstanding, how much are held by member banks, and how much by all banks. Even if Fed membership were to drop to zero and if no banks were required to hold reserves, any creation of "transaction accounts" would require depository institutions to hold some kind of providential reserves in the form of monetary base items to meet liquidity demands by other depository institutions and depositors. Since the Fed manufactures virtually all of the monetary base, which is in

turn required for the existence of any common money, Fed control is complete no matter what volume of reserve balances is held at Fed Banks.

The Fed solution to the membership problem was to encourage Congress to make reserve requirements mandatory for all depository institutions. H.R. 7, S.85, and the bill that finally passed both Houses of Congress, H.R. 4986, contained this provision. Institutions so affected could still choose to remain nonmembers of the Fed, but they would all have to keep zero-interest reserve accounts with Fed Banks. In addition, they would all be entitled to enjoy the privilege of the discount window.

This perquisite was emphasized in Fed testimony. Use of the discount window had shrunk, noted Miller, due to membership attrition. Nevertheless, the window was still "the lender of last resort" to the payments system. "If the proportion of institutions having access to this facility were to decline," he warned, "individual institutions...could not...cushion temporarily the impacts of restrictive monetary policies.... Thus, the Federal Reserve may find that its ability to limit growth in money and credit in order to curb inflation was being unduly impeded because the safety valve provided by the discount window was gradually losing its effective coverage" (p. 230).

Miller's final argument is absurd. The Fed's powers to promote inflation, as well as to abate inflation, have nothing to do with the discount window. Furthermore, his remarks state that the Fed can "limit growth in money and credit in order to curb inflation" without a discount window and without direct control over bank reserves.

In any case, the contemporary Fed has powers far beyond the scope of discount window accommodation. It creates monetary base constantly and positively, not just when an occasional bank needs extra liquidity. To put it baldly, virtually every hour of the day the Fed is acting as a "lender of last resort" by creating notes and reserves via open market purchases of government securities. In this holistic creation of money, the role of the discount window is negligible. The monetary base at the end of 1980 was \$155 billion

while loans to member banks at this time were less than \$1.5 billion. As a source of monetary base material, discounts to member banks were therefore less than 1 percent of the total.

Not only has discounting become a negligible sideline of Fed policy in the creation of monetary base, but banks have a much broader area in which to market their reserve needs or bounties—the Federal funds market. The activity in this market swamps the minor operations of the discount window. Fed funds and repurchase agreements just for large member banks were around \$108 billion in late 1980, compared to less than \$1.5 billion in Fed loans to members (*FRB*, 1981, p. A6).

No essential function in the payments system would be harmed in the slightest by the abolition of the discount window. It is an anachronism. Its only "function" is to act as a Federal Reserve showpiece—a public relations device to suggest to Congress, the media, and the general public that the Fed is some kind of an insurance agency against financial disaster.

### III. Federal Reserve Note Collateral

One of the more intriguing sections in Title I of the DIDMCA comes under the subsection labeled "Miscellaneous Amendments." It expands the "eligible collateral" provision for Federal Reserve notes outstanding to include the fully guaranteed obligations of a foreign government or the agency of a foreign government, as well as any other financial assets that may be purchased by Reserve Banks (*FRB*, 1980, p. 448). The question implied by this provision is, why would the Fed need more collateral for notes when it could already monetize unlimited quantities of government securities that were all eligible collateral?

The bill H.R. 7, when first put together in 1979, had no provision for any change in collateral allowances. Congressman Ron Paul noted that only in the third version of H.R. 7 did the collateral provision surface for the first time, "but...without one word of [formal] testimony from the Fed" (*CR*, 125, 1979, pt. 15, p. 19678).

The Fed had quietly worked in the amendment at the conference committee meetings (*CR*, 125, 1979, pt. 15, p. 19678). Congressman William Stanton of Ohio noted that the amendment had been "added to the bill at the last moment without any testimony from the Fed or any other witness" (*CR*, 125, 1979, pt. 15, p. 19679). The objections of Paul, Stanton, and others succeeded in getting the collateral amendment deleted. The bill then passed the House by a vote of 340-20 (*CR*, 125, 1979, pt. 15, p. 19690).

In the next session of Congress the bill (H.R. 4986) that ultimately became the DIDMCA of 1980 was introduced. It was debated in both Houses, and ended up in another House-Senate conference committee to resolve disagreements. The conference committee report then went back to each House for consideration.

Even though the final bill mandated universal reserve requirements controlled by the Fed, it also anticipated a general reduction of reserve requirements overall to a uniform value around 12 percent. Such a reduction implied that total reserve balances kept at Federal Reserve Banks, plus vault cash reserves in the form of coin and Federal Reserve notes, would probably decline (the Fed estimated) by about \$15 billion. This change was to take several years so that depository institutions would experience no immediate hardships or windfalls.

When Senator Proxmire presented the bill to the full Senate, the provision that anticipated reduction of reserve balances at the Fed had suddenly become a "problem" requiring the re-inclusion of the infamous collateral provision. The reason for Proxmire's "problem," however, resulted from his programmed misinterpretation of the Fed's procedures for creating money. "A portion of the Federal Reserve's securities portfolio," he explained, "...represent[s] purchases made [by the Fed] *with reserves deposited by member banks*. Since the Monetary Control Act would release [sic] about \$15 billion in reserves, a comparable amount of securities would need to be sold. This would reduce the collateral available for Federal Reserve notes [!]." Such a reduction, Proxmire con-

tinued, could proceed to the point where the Fed had inadequate collateral for the issue of notes. The supplementary collateral provisions in the bill would alleviate this "technical" problem (*CR*, 126, pt. 6, 1980, p. 6897, emphasis added).

In the House debate over H.R. 7 several months earlier, Chalmers P. Wylie of Ohio had similarly "explained" the Fed-commercial bank relationship to his House colleagues: "The banks hold some of these reserves [created by open market operations] as vault cash and the rest goes *into* the Federal Reserve System which it uses for investments—the return from which goes to the Treasury of the United States [sic]" (*CR*, 125, pt. 15, 1979, p. 19669, emphasis added). With these "explanations" of Fed operations, any resulting legislation could hardly be rational.

Volcker had earlier testified before Proxmire's committee and had cultured this twisted "explanation." Reductions in reserve requirements for depository institutions, he had stated, "could be technically unworkable because [they] might result in insufficient amounts of...eligible financial assets to meet the collateral requirements against notes." The House, Volcker observed, had rejected the extension of collateral provisions in the H.R. 7 bill. To meet these objections, he suggested adding to the present list "only assets acquired abroad arising from time to time out of our foreign currency operations." Specifically, he wanted "short-term foreign government securities" (1979, p. 828). In a later statement made on February 4, 1980, Volcker again mentioned the "problem," and volunteered that "...we are prepared to supply an appropriate amendment that could be attached to any bill that would deal with the problem" (p. 147).

The Conference Committee received the amendment and accepted Volcker's rationale for it. As everyone acquainted with Fed operations knows, the money-creating process works exactly opposite the way "explained" by Proxmire and Wylie. As the Fed buys the securities, it perforce creates member bank reserve accounts or Federal Reserve notes for which the government securities serve as

collateral. The Fed can never be short of collateral for its monetary base "obligations" because it has always created exactly the same dollar amount of monetary base as the dollar value of the securities it has purchased.

Regardless of collateral, Federal Reserve notes are "legal tender for all debts, public and private." Eligible collateral is at best simply a security provision that limits the items the Fed is allowed to monetize. It is a leftover from the time 50 to 70 years ago when the notes were not legal tender and the Fed was an entirely different kind of institution. Collateral security is a pointless flourish for legal tender currency.

Actual experience since the passage of the DIDMCA indicates that no problem would have arisen (as indeed it *could* not) with only conventional collateral available for Fed notes. Even though reserve accounts at Fed Banks did decline as reserve requirements were phased down toward 12 percent, the Fed's consolidated statement during the period 1981-84 never showed less than an excess of \$9 billion in conventional collateral over the outstanding issues of Federal Reserve notes (*FRB*, 1981-83, Tables 1.18, p. A-11).

After the DIDMCA of 1980 had been operational for a few years, Charles Partee of the Federal Reserve Board appeared again before the House Banking Committee and reported on the Fed's use of the new collateral provision. He noted that Fed holdings of foreign currencies "arose as a result of active intervention in foreign exchange markets by the Treasury and the Federal Reserve..." (1983, p. 194). On January 1983, such holdings were \$5.3 billion, primarily composed of German marks, Swiss francs, and Japanese yen. Partee suggested that the substance of the Monetary Control Act and the responsible policy attitude of the Fed were "ample safeguards to prevent section 105(b)(2) from being used by the Federal Reserve as a basis for assisting governments in financial difficulties" (1983, p. 195). Yet in the next paragraph, he admitted that part of the Fed's holdings were Mexican pesos acquired in connection with the Bank of Mexico's drawing on the \$325 million swap

arrangement with the Federal Reserve. The peso holdings were then "invested" in an interest-bearing account at the Bank of Mexico. "When the swap drawing is unwound," Partee assured the committee, "the pesos will be exchanged with the Mexican central bank for dollars at the same rate of exchange at which they were acquired" (1983, p. 195). However, the income report of the Federal Reserve Banks for the year 1983 has the following deduction from current income: "\$456 million of unrealized loss on assets denominated in foreign currencies related to revaluation of the assets at market exchange rates" (*FRB*, 1984, p. 109).

#### IV. Conclusion: The Inevitability of Federal Reserve Power

The overwhelming votes by which the DIDMCA of 1980 passed both Houses of Congress primarily reflected the deregulatory aspects of Title II rather than the augmented powers of the Fed under Title I. Most congressmen simply "checked out" on the vote because they favored more and fairer competition in the financial industry.

Since the Federal Reserve already had complete control over the monetary system, the DIDMCA of 1980 could not augment the Fed's money-creating powers. The Act, however, extended the Fed's regulatory powers over the financial system and it added to the Fed's ability to intervene in foreign affairs by buying and monetizing foreign government obligations. It therefore put the Fed into the role of a silent partner, or even a surrogate, of the State Department for bailing out bankrupt foreign governments who had unmanageable debts due to several large banks in the United States.

Fed officials in their testimony to congressional committees persistently and doggedly advanced one major theme: the Fed had to have more power—to fight inflation, to prevent chaos in the financial industry from deregulation, and to act as an insurance institution for failing banks who might drag other institutions down with them. By misdirection and subterfuge, the Fed inveigled an unwary Congress into doing its bidding. The

Fed's success serves as an object lesson in demonstrating the ineffectiveness of legislative checks on the scope of policy actions assigned to an agency with discretionary powers.

# Deregulation and Monetary Reform

By LELAND B. YEAGER\*

In the past we could distinguish sharply between currency and checkable deposits, on the one hand, and savings accounts and other near- and nonmonies, on the other hand. Unambiguously defining money and measuring its quantity has now been growing more difficult. Inflation-boosted nominal interest rates have promoted wriggling around requirements for non-interest-bearing reserves and around interest rate ceilings. Responses include money market funds, money market deposit accounts, NOW and Super-NOW accounts, overnight repurchase agreements, aspects of the Eurocurrency market, and cash-management accounts offered by brokerage houses. Deregulation has been blurring the distinction between banks and non-banks and between things that do and things that do not function as media of exchange.

The late Robert Weintraub, among others, used to argue (1984, for example) that despite institutional changes, the functional relation between nominal *GNP* and the quantity of money will remain stable—money being properly defined. Adjusted definitions and adjusted demand or velocity functions can continue yielding good fits. Weintraub expected continuing success with money defined as fully checkable accounts in depository institutions plus currency in circulation and nonbank travelers' checks.

But does such a possibility warrant confidence in being able to conduct a quantity-oriented monetary policy from month to month and day to day? What accounts should be deemed *fully* checkable? Which institutions count as *depository* institutions? Figuring out, *ex post*, how money should have been defined and regulated is not the same as knowing how to do so currently. (Thomas Simpson, 1984; John Wenninger, 1984; and Gillian Garcia, 1984, offer recent discussions by Federal Reserve economists.)

Robert Hall (1982) has expressed skepticism about the old idea of quantity control:

...[M]onetary regulations imposed by the American and British governments of the past century create a more-or-less stable relation between a certain class of assets called money and nominal spending..., but different regulations would alter that relation. [p. 1552]

Regulation of financial institutions ...had...implications for the stability of the demand for money. ...[M]ost important, a wide variety of methods of carrying out transactions and holding wealth were regulated out of existence. [p. 1554]

...the money stock itself is a creature of inefficient regulation. [p. 1555]

I do not say that the monetarists were wrong in advocating their steady-growth rule. But their remedy was not taken in due time, the disease has grown more complicated, and their old prescription may no longer be the best.

Rolling deregulation back might conceivably restore stable links between money and other variables. However, deregulation is no mere product of ideology. Regulations have been succumbing to powerful market incentives not easily overcome. Conceivably, also, new monetary linkages might stabilize after the current process of transition has run its course. Who can foretell the future?

## I. The BFH System

Prudence recommends being ready: we should contemplate radical alternatives to our existing and changing monetary regime. Even reforms never adopted may provide contrasts affording insights into our present unsatisfactory method of giving determinacy to our unit of account.

The unit in which we quote prices, express debts and terms of other contracts, and keep accounts is the value of the dollar of fiat money, the scruffy dollar bill. This unit is analogous to units of weight and length and is at least as often used in everyday activities.

\*Auburn University, Auburn, AL 26849.

Yet its size is determined in a haphazard, precarious, and downright preposterous manner.

I wish time permitted detailing the absurdities of making our unit of account be the supply-and-demand-determined value of the unit of the fiat medium of exchange. Supply and demand fail to balance smoothly and continuously because they do not meet on a specific market and determine a specific price. "The money market" is just a figure of speech, not a reality; so monetary disequilibrium gets corrected only in a roundabout and often painful way.

One radical contrast with our existing system appears in what Robert Greenfield and I (1983) have called the BFH system (crediting Fischer Black, Eugene Fama, and Robert Hall for ideas borrowed). The unit of account would no longer coincide with the unit of the medium of exchange. No homogeneous medium of exchange would exist as a possible rival unit. The government would define the new unit, just as it defines units of weights and measures. The definition would run in terms of a bundle of commodities so comprehensive as to have a nearly stable value against goods and services in general. The items in the bundle would be precisely specifiable ones with continuously quoted prices.

The government would exert a nudge against the inertia of old practices by conducting its own transactions and accounting in the new unit. The government is bound to influence a new system by the particular way it disengages from its domination of the current one, so policymakers can hardly avoid considering what sort of reform is desirable. Apart from promoting the new BFH unit, the government would practice *laissez-faire* toward the financial system. It would be forbidden to issue money. (The reform is quite different from the often-proposed composite-commodity money.)

Deregulation would give full scope to innovative financial intermediation. Private enterprises would, in effect, repackage investment portfolios into convenient media of exchange. No one can confidently predict future details. It seems likely, though, that institutions would emerge combining the fea-

tures of today's banks, money market funds, and stock mutual funds. Some holdings in these institutions would presumably be dividend-yielding equity shares; others would be accounts denominated in the BFH unit and bearing interest at competitive rates. In either case, people would not only stipulate prices and payments but also write checks on these holdings in the single, precisely defined, stable unit, *not* in heterogeneous goods and securities.

Would checks drawn on and deposits in financial institutions be redeemable? (The same question applies to currency, for some institutions would presumably issue notes and even coins denominated in the BFH unit.) It is unlikely—because so awkward—that institutions would offer and customers demand redemption in bundles of the actual commodities defining the unit. "Indirect redeemability," as James Buchanan has suggested calling it, is more likely. Competition might lead institutions to cash checks and redeem their currencies and deposits in whatever quantities of gold or of specified securities equalled in total value as many standard commodity bundles as the numbers of units of account denominating the obligations to be redeemed.

It is important that institutions would similarly settle net balances due on account of checks (and banknotes) presented at their clearinghouse. They would transfer gold or securities actually worth as many commodity bundles as the numbers of units of account to be settled. Professionals would make and implement the required calculations every business day, and the ordinary person would no more need to know just what determines the purchasing power of the BFH unit than he needs to know what determines that of the dollar nowadays.

Furthermore, routine settlements at the clearinghouse would provide part of the scope for arbitrage that would maintain the operationality of the unit's commodity definition. Suppose, with Arthur Okun (1981, p. 290), that the standard bundle consists of 1 ball + 1 orange (the principle illustrated is the same with a multi-item bundle). Suppose, further, that market forces make 1 ball worth 3 oranges. Then the BFH unit is worth  $1\frac{1}{3}$

balls and, equivalently, 4 oranges. Prices are *U*.75 for a ball and *U*.25 for an orange, totaling *U*1, as they should. Any discrepancy would provide an opportunity for profitable and corrective arbitrage. Numerical examples could readily be given if space permitted.

Although practices under the BFH system would displace money as we now know it, they would not entail the textbook inconveniences of barter. The advantages of a single definite unit of account and convenient methods of payment would be retained and enhanced. Apart from crucial differences in the unit and in the media for redeeming their obligations, financial institutions would be practicing something similar to free banking under a gold standard. (On the success of free banking in Scotland up to 1845 and for analysis, see Lawrence White, 1984.)

With the unit of account and media of exchange divorced, the unit's value (like the meter's length) would be established by definition, not by regulation of any quantity. Quantities of media of exchange would be limited by the real (unit-of-account) quantities people were willing to hold. Quantities would be constrained in much the way operating for mutual-fund shares nowadays, for nearmoneys until the recent blurring of the distinction between them and circulating media, and for money itself in an individual small country to which the purchasing power of its unit is dictated under an international gold standard. The sizes of the asset sides and the liability and equity sides of institutions' balance sheets would be influenced and reconciled largely by market-determined interest and yield rates received on the institutions' loans and investments and paid to their depositors and shareholders.

Trouble in understanding this demand-side (as well as supply-side) limit to quantities stems, I conjecture, from carrying ideas over from our present system of fiat money, whose unit is also the unit of account. Under this system, expansion of the nominal supply causes the nominal amount demanded to increase also through shrinkage of the unit's real size. Things would be quite different with a unit defined without reference to any medium of exchange.

With quantities of media of exchange determined by demand and supply and with checkable deposits and equity holdings in financial institutions having market-clearing flexible yields or prices of their own expressed in the BFH unit, monetary disequilibrium as we have known it could no longer occur. With the value of the unit of account spared from sometimes coming under strong but sluggishly working upward or downward pressure, painful macroeconomic disorders would be practically forestalled.

Beside macroeconomic advantages, the BFH system would provide the monetary saturation whose absence concerned Milton Friedman in his 1969 article, "The Optimum Quantity of Money." Since media of exchange would bear interest or dividends at competitive rates, high opportunity costs would no longer press holders to spend real resources economizing on cash balances.

A further advantage is absence of any base money distinct from more abundant ordinary money. No longer could scrambles to get out of ordinary money into base money cause panics and deflation. Any distrust would be concentrated on specific financial institutions. Investments in them would decline in price and quantity. Competition would favor the more prudently managed institutions. Deregulation would appropriately extend to abolishing government deposit insurance.

Mention of base money reminds us of perhaps the greatest difficulty with the BFH system, that of making the transition. The appearance of attractive alternatives would collapse the demand to hold money of the present type. Holdings of and liabilities on bank-account dollars would pretty well match. The problem is the collapse of demand for Federal Reserve notes and deposits and Treasury coins. Either this base money would lose its value, expropriating its holders, or else the government would have to replace it by ordinary, interest-bearing, burdensome government debt.

I see no satisfactory answer to this problem of transition. Still, the BFH system is worth understanding for the light it sheds on our existing system. Furthermore, if the existing dollar should be destroyed anyway—perhaps by persisting government fiscal irre-

sponsibility—it would be a shame to reconstruct the same old failed system.

## II. Fisher's Proposal, Modified

The awkwardness of shifting away from government money recommends considering a second-best reform. Abandoning any quantity rule, it would combine a price-index rule with gold redeemability in a manner reminiscent of Irving Fisher's "compensated dollar." (See Fisher, 1920, and compare Willford King, 1948, pp. 209–10. The present proposal differs from Fisher's only in details and in the rationale offered.)

The monetary authority would be required not only to target on a comprehensive price index but also to redeem its money on demand in the (changeable) weight of gold actually worth, at current prices, the bundle of goods and services used in specifying the index. The authority would also be required to issue new money in exchange for the calculated amount of gold, with perhaps a slight spread between its selling and buying prices of gold to cover expenses.

The standard objection to irredeemable fiat money managed so as to stabilize a price index centers on lags and the attendant danger of overshooting and of oscillations around the target. Lags supposedly intervene between an incipient money-supply-and-demand imbalance and its reflection in the price index and between movements of the index and policy responses and their corrective effects. Under the system suggested here, though, two-way convertibility plus arbitrage would keep the dollar always equal in value to the (variable) quantity of gold that was in turn equal in value to a specified bundle of goods and services. The problem of lags would thus be circumvented (or so it seems to me).

Convertibility of the sort described would tie the dollar to the specified bundle. The system would not be a gold standard. Some other commodity, or some one or more securities, might well be the redemption medium instead; gold serves here only as an example. No such self-aggravating and devastating scramble for gold could occur as can occur under an ordinary gold standard with

fractional reserves. Any scramble would reflect itself in an increased price of gold both in money and relative to other goods and services, thereby automatically reducing the physical quantity of gold in which the dollar was redeemable.

Incidentally, the monetary authority would not necessarily be restricted to issuing and retiring money only against quantities of redemption medium offered by or demanded by the public. It could aim open market operations in securities at stabilizing the price index directly and so hold down the volume of actual conversions. Still, two-way convertibility would be available to keep the dollar stable against commodities.

Convertibility of this sort would be more than merely decorative. It would impose an additional discipline on the monetary authority by requiring it actually to *do something* at the initiative of money holders. If excessive money creation had raised the price index from the target level of 100 to 120, people would be redeeming money of \$100 face value in gold (or other redemption medium) quoted at \$120, selling the gold for \$120 and redeeming that money in gold worth \$144, and so on. Threatened with running out of gold, the government would have to buy more. In bidding up the dollar price of gold, it would be tending in that particular way to hold down the physical quantity of gold in which the dollar was redeemable. To avoid further debasing the purchasing power of money and further endangering its gold reserves, however, the government would have to pay for its gold purchases otherwise than by issuing or reissuing money. It would have to raise the necessary funds by cutting expenditures or by taxes or noninflationary borrowing. Such discipline would constrain overissue in the first place.

Monetary management would no longer depend on accurate conceptualization, measurement, and regulation of the quantity of money. The logic of this system of a modified compensated dollar, like the logic of the BFH system, would recommend complete deregulation, including free banking. By the way, the BFH system might be interpreted as a nongovernmental, decentralized, and competitive version of the system just described.

# Speculation, Deregulation, and the Interest Rate

By LEONARD A. RAPPING AND LAWRENCE B. PULLEY\*

Interest rates during the 1980's have been at average levels unprecedented in both Europe and the United States since the beginnings of the Industrial Revolution. For those who believe that the Fed controls the interest rate, these high rates are attributed to the October 1979 decision to target bank reserves rather than interest rates. In this view, the Fed succeeded in its effort to indirectly regulate the interest rate by restricting bank reserves, and hence credit. However, because financial innovation (for example, NOW and money market accounts) has greatly weakened the link between reserves and credit, we reject this view. We propose instead that the abnormally high interest rates resulted from portfolio or asset adjustments in response to interest rate deregulation (the October 1979 decision as well as the decontrol of interest rates on deposits) coupled with generalized speculation in asset markets. This explanation will be empirically contrasted with the loanable funds explanation which stresses the flow supply and demand for credit and the Fisher-Friedman explanation which stresses inflationary expectations.

## I. The Theory<sup>1</sup>

When severed from the rate of profit, the rate of interest is sometimes viewed as resulting from a portfolio choice between bonds and money. Under these circumstances, the interest rate will depend among other things on the market's expectation of the future rate of interest. Of course, uncertainty about the future imparts an unavoidable element of arbitrariness in determining the interest rate. However, under normal circumstances the

market will form a conventional view of what the rate of interest will be—based largely on evidence from the recent past. As long as the conventional view prevails, speculators act to stabilize the market. However, when the normal structure is disrupted, destabilizing speculation can drive the prices of assets far outside their conventional range, leading to the breakdown of the convention and to expectations that the unwarranted price movement will continue.

Between 1969 and 1977 the long-term rate of interest on Treasury bonds fluctuated between 6 and 7 percent—due to the Fed's policy of pegging interest rates as much as to the market's belief that such a policy would continue. For eight years the convention held and stabilizing speculators were appropriately rewarded for their activities. But in 1978 the long rate started to drift up, and a year later the Fed renounced the policy of pegging interest rates. Some speculators, whose stabilizing activity had been based on the Fed's policy of targeting interest rates, were driven out of the market entirely. However, because it was understood that the Fed's abandonment of interest rate targets and the continued decontrol of deposit rates were signaling higher interest rates and a recession, many others were converted to destabilizing bears. The long rate both rose and became unstable.

Although this simple Keynesian approach is insightful, classification of assets into the two categories, money and bonds, fails to illuminate the effects of decontrol. For the purpose of analyzing the decontrol of interest rates, the dividing line must be fixed between those assets whose returns were regulated (bills, bonds, and deposits) and those assets in which returns are uncontrolled (gold, foreign exchange, equities, real estate, and real goods).

Rapping (1979) has argued that a form of destabilizing speculation (i.e., seeking short-term profits by betting on self-sustained asset

\*University of Massachusetts, Amherst, MA 01003, and Brandeis University, Waltham, MA 02154, respectively.

<sup>1</sup>The discussion in this section draws selectively on an unpublished paper by Rapping and Stephen Bennett (1983).

price changes and disregarding fundamentals) and generalized inflation are common in periods in which the social conventions governing the distribution of income and wealth erode and distributional conflict results. Under these circumstances, relative prices change and economic growth is slow and problematic. With the combination of conflict, rapidly changing relative prices, and slow growth, speculation abounds. The gambling spirit infects the markets for real estate, equities, collectibles, gold and foreign exchange to name the more prominent speculative vehicles of recent years.

The expectation (if not always the reality) of very high returns now dominates behavior. Under these circumstances, the regulation of interest rates will prevent the self-generating increase in the prices of speculative assets from raising the interest rate. However, once interest rates are deregulated, the return on interest-bearing assets will rise in accordance with the high returns expected on speculative assets. Depending on attitudes toward risk, the interest rate might not equal the anticipated yield on the speculative assets.

We refer to the explanation of high interest rates described above as the portfolio or asset-preference explanation, in which prices move in order to equilibrate the demand for a stock of assets to the available supply. The most widely held alternative view is based on the flow supply and demand of credit or loanable funds. In this approach, the demand for credit depends on prices and the scale of output, while the supply of credit depends on the voluntary savings of the public and on the amount of new credit creation by the banking system.

A third explanation for high interest rates is that the prospect of inflation or expected inflation affects the present by raising the current nominal rate of interest. In this long-run competitive equilibrium view, the interest rate is a result of technology interacting with culture and expected inflation rates, all of which determine the investment and savings decisions of a society. Savings decisions result from the choice between present and future consumption while investment decisions are based on expected profitability. The

expectation of inflation will be impounded in current savings and investment decisions in such a way as to raise the nominal interest rate in proportion to the expectation of inflation.

## II. Methodology and Results

### A. The Model

In expectations form, the basic Fisher equation relating the nominal interest rate,  $R$ , expectations of the real rate,  $r$ , and expectations of the inflation rate,  $\pi$ , can be written

$$(1) \quad R_t = E_m(r_t | \phi_{t-1}) + E_m(\pi_t | \phi_{t-1}),$$

where  $\phi_{t-1}$  represents the relevant information set available at the beginning of period  $t$  and  $E_m$  represents market expectations. Assuming the distribution of  $E_m(r_t | \phi_{t-1})$  to be centered on a constant long-run equilibrium rate,  $\rho$ , with short-term fluctuations given by  $u_t$ , (1) becomes

$$(2) \quad R_t = \rho + E_m(\pi_t | \phi_{t-1}) + u_t.$$

The earliest attempts to empirically examine Fisher interest neutrality have focused on (2) above, regressing nominal interest rates on actual or lagged inflation rates or some measure of expected inflation. The results have not been satisfactory. Coefficients on expected inflation are often significantly less than the predicted value of one, and vary across both time periods and maturities.

In response to mounting evidence that the expected real rate itself is not constant, recent studies have allowed changes in the real rate to be associated with changes in a number of other variables (often in the context of general equilibrium macroeconomic models). John Carlson (1977a) and Vito Tanzi (1980) examine the effects of changes in real activity or business cycle behavior (i.e., shifts in the *IS* curve). In downturns, for example, the (expected) real return to capital falls. If, as a consequence, the demand for loanable funds falls more than the supply, the (expected) real interest rate falls. Of course, if shifts in the *IS* curve can affect real rates, so should

shifts in the *LM* curve. James Wilcox (1983) and others have included money supply growth as a proxy for the well-known liquidity effect. Some have suggested increased money growth volatility as an explanation of high rates, but David Berson (1983) argues that interest rate volatility is the more important volatility measure, particularly given the role of risk premiums in the finance literature.

In this paper we employ the augmented Fisher relationship to examine the hypotheses presented in the introduction and detailed in Section I. The model we adopt is the following:

$$(3) \quad R_t = E_m(r_t|\phi_{t-1}) + \beta_1 E_m(\pi_t|\phi_{t-1}) + u_t,$$

$$(4) \quad E_m(r_t|\phi_{t-1}) = \rho - \beta_2 E_m(\pi_t|\phi_{t-1}) - \beta_3 LIQ_t + \beta_4 ACT_t + \beta_5 \sigma_{R_t} + v_t,$$

where  $E_m(\pi_t|\phi_{t-1})$  is included among the explanatory variables in (4) to allow incomplete adjustment to the level of expected inflation. *LIQ* is a liquidity variable reflecting shifts in the *LM* curve, *ACT* is a real activity variable for shifts in the *IS* curve, and  $\sigma_{R_t}$  is a measure of interest rate volatility to incorporate changes in the risk premium.  $\rho$  is the constant component of the expected real rate. All *beta* coefficients are expected to be positive.  $\beta_1$  is not constrained to unity to allow for tax effects. Combining (3) and (4) yields

$$(5) \quad R_t = \rho + \beta_0 E_m(\pi_t|\phi_{t-1}) - \beta_3 LIQ_t + \beta_4 ACT_t + \beta_5 \sigma_{R_t} + w_t,$$

where  $\beta_0 = \beta_1 - \beta_2$  and  $w_t = u_t + v_t$ . With a suitable proxy for  $E_m(\pi_t|\phi_{t-1})$  (5) can be estimated with ordinary least squares.<sup>2</sup>

<sup>2</sup>Of course, no available measure of  $E_m(\pi_t|\phi_{t-1})$  can be expected to be error free so an errors-in-variables problem exists. However, as Tanzi has shown, the coefficients do not seem to be particularly sensitive to the use of the Livingston survey data and *OLS* or any of several instruments and *2SLS*. Since the Livingston data will be used in this study, we note the finding of Kajal Lahiri and Mark Zaporowski (1984) that the Livingston data consistently underpredict true expectations, in which case coefficients based on the Livingston data are overstated.

We now relate the model described above to the explanations of high interest rates previously discussed. Expression (3) is the simple inflationary expectations model. The liquidity and real activity variables in (4) capture the effects of the Keynesian money-bonds asset choice and changes in the demand for loanable funds. Interest rate volatility is included to control for risk. In Part C below, we present evidence that the inflationary expectations and loanable funds models do not explain interest rates after October 1979. Furthermore, the reported significance of a naive shift variable is consistent with the presence of increased speculative activity.

### B. The Data

The expected inflation series is based on the Livingston surveys computed by the method described in Carlson (1977a, b). The survey represents an average of predictions by economists of the value of the *CPI* six months from the survey months of June and December. Therefore, the nominal interest rates used in this study are the six-month Treasury bill rates prevailing in those months. The period consists of the fifty observations 1959:6 through 1983:12.

The liquidity variable (*LIQ*) is measured as the growth rate in seasonally adjusted and revised *M1* (current dollars) over the most recent quarter. For example, the value corresponding to the June observation is the growth rate implied by the first- and second-quarter observations on *M1*. The measure of real activity used is the growth rate in real *GNP* over the last six months (two quarters).<sup>3</sup> A measure of interest rate volatility,  $\sigma_{R_t}$ , is computed as the standard deviation of monthly observations on three-month Treasury bill rates over the most recent twelve-month period.<sup>4</sup>

<sup>3</sup>In this model, federal tax and spending behavior influence the interest rate by their impact on economic activity. This by no means exhausts the avenues whereby the deficits might affect the interest rate. In particular, deficits could alter interest rate expectations and asset pricing behavior.

<sup>4</sup>The three-month rates were used rather than the six-month rates because the monthly observations on these rates were more readily available. The Livingston

## C. Results

To examine the hypotheses described above, we construct the model in (5) above with a duplicate set of explanatory variables (including the constant) which take on the value zero through 1979:6. With these changes the estimating equation becomes

$$(6) \quad R_t = (\rho + \rho') + (\beta_0 + \beta'_0)E_m(\pi_t|\phi_{t-1}) \\ - (\beta_3 + \beta'_3)LIQ_t + (\beta_4 + \beta'_4)ACT_t \\ + (\beta_5 + \beta'_5)\sigma_{Rt} + w_t,$$

where the primed values represent changes in the coefficients after October 1979. A positive and significant value of  $\hat{\rho}'$  would be consistent with our hypothesis that after October 1979, traditional economic relationships in interest rate determination were replaced by what we have labelled speculative factors. These influences helped keep interest rates abnormally high. (Unfortunately, this test is not very powerful since a positive  $\hat{\rho}'$  could result from some other omitted variable or influence.)

Table 1 presents the results of estimating various versions of (6) above using an iterative maximum-likelihood procedure to correct for first-order serial correlation. Credit controls were in effect during the first half of 1980. Therefore, a dummy variable taking the value one for 1980:6 was included to avoid any distortions introduced by these controls. All variables with the exception of expected inflation were reduced by their sample means. The constant terms can therefore (roughly) be viewed as the real rate when inflationary expectations are zero and  $LIQ$ ,  $ACT$ , and  $\sigma$  take on their sample mean values.

Column 1 of Table 1 gives estimates of the basic Fisher relationship. The estimates in column 2 are from the model in (5) when coefficients are not allowed to adjust in the post-1979 period. The model in column 3

<sup>e</sup>Iterative *ML* estimates of the first-order serial correlation coefficient.

differs from that in column 2 by the inclusion of a dummy variable for the post-1979 period. Column 4 contains estimates for the full model in (6).

Consider the results in Table 1. The unprimed values are consistent with our expectations and with the results of other studies. The one notable exception is the statistically insignificant coefficient on the real activity

survey data are from the Federal Reserve Bank of Philadelphia. The interest rate and money supply data are from the Federal Reserve. The *GNP* figures are from the Department of Commerce.

variable.<sup>5</sup> There is also some evidence of coefficient adjustments after 1979. The adjustment on the *LIQ* variable coefficient ( $\hat{\beta}_3$ ) indicates a possible increase in the importance of the liquidity effect. This lends some support to the conclusion of Richard Clarida and Benjamin Friedman (1984) regarding the contribution of slow money growth to the recent high rates. The negative coefficient adjustment on expected inflation ( $\hat{\beta}_0$ ) is consistent with the view that interest rates have continued to rise (or remain high) in the post-1979 period despite declines in actual and expected inflation. Therefore, it may not be reasonable to posit lagging inflationary expectations as a reason for the high rates.

One potentially troublesome aspect of the results in Table 1 is the large and statistically significant first-order serial correlation coefficient (prior to correction). Although some serial correlation is often present in analyses over time, such large values could indicate the omission of an important variable from the analysis of the post-1979 period. Of course, the dummy variable included for the period is at best an imperfect proxy for the factors we describe in Section I. Furthermore, the residual serial correlation is not a product of the post-1979 period alone. When expression (5) is estimated for the period 1959:6 through 1979:6, the computed serial correlation coefficient is .70.

There is evidence in Table 1 for our assertion that a substantial component of the increase in interest rates since October 1979 cannot be explained by the model in (5), even when all slope coefficients are allowed to adjust. The coefficient  $\hat{\rho}$  is positive and statistically significant. Furthermore, the average of the last nine residuals (observations 1979:12–1983:12) for the model in column 4 is .06. If  $\hat{\rho}$  is constrained to be zero and the model in column 4 is reestimated, the average of the last nine residuals becomes .48. (Based on the residual standard deviations, the standard deviations of both these averages is approximately .25.)

<sup>5</sup>As an additional proxy for real activity, the ratio of employment to non-institutional population was used. The measure is employed by Carlson (1977a), but produced results no different from those in Table 1.

### III. Conclusions

Recent high interest rates are not explained by factors which appear in traditional interest rate models. Similar results have been found in the study of foreign exchange markets where neither the purchasing power parity flow approach nor the interest differential asset approach can account for the behavior of the dollar after 1977. Some have attributed the high value of the dollar to speculative behavior in which decision making is contaminated by a crowd psychology. We contend that while direct speculation in assets fixed in money terms may account for high interest rates, the high rates may also be attributed to generalized speculative activity throughout the economy which pulled interest rates up once they were decontrolled.

Of course, our empirical evidence is only suggestive. With the usual caveats of caution, we conclude that unless speculation is penalized or otherwise deterred, continued deregulation of interest rates could mean continued high interest rates. The excessive speculation of the 1920's was penalized in the bath of red ink caused by the financial market panic of 1929–33. In the 1980's, on the other hand, the Fed has wisely renounced this dangerous medicine for financial overexuberance. Unlike the earlier period, it has actively played its role as a lender-of-last-resort. Of necessity, selective penalties are now needed and the authority to administer them will require some relaxation in the process of financial market deregulation.

## YESTERYEARS' LONG-RANGE PROJECTIONS: A RETROSPECTIVE

### 1985 Projections of the New York Metropolitan Region Study

By DICK NETZER\*

In 1960, the Harvard University Press published *Metropolis 1985*, the final volume presenting and interpreting the results of the New York Metropolitan Region Study, written by the study's director, Raymond Vernon. The study was a three-year effort conducted by Harvard's Graduate School of Public Administration (now the Kennedy School of Government) for the Regional Plan Association of New York. The specific output of the study was twofold: nine volumes of urban analysis and an elaborate set of economic and demographic projections from a mid-1950's base to 1985, to form the foundation for a new regional plan for the 22-county metropolitan region. The first Regional Plan for New York and Its Environs—the first regional plan anywhere—had been produced between 1922 and 1929 and had been founded on a pioneering economic study directed by Robert Murray Haig of Columbia.

The 1956–59 study was one of a series of large-scale regional studies (and much the largest and most ambitious of that series) done in the late 1950's and early 1960's with financing by the Ford Foundation and other foundations and, in reality, inspired by Ford. The methodological contributions of the New York study were considerable: among other things, it pioneered in the regional application of input-output analysis, in regional population projection techniques and in the application of factor analysis to local government expenditure. The study and the contemporaneous work of Edgar S. Dunn, Jr. (see Harvey Perloff et al., 1960) were the first empirical uses of the "shift-share" analysis that became a basic technique of regional economics. Indeed, the study formed a major

component of the technical foundation of the empirical side of urban and regional economics, then in its infancy.

However, the purpose here is not to review the technical contributions of the study. Instead, this paper compares the picture of the New York region painted in the study with the realities as of the early 1980's (usually 1981, to avoid economic data that reflect the deep 1982–83 recession), to address three questions. First, how different are the American economy and the economy of our largest urban area from the forecasts made by the best of analysts a quarter-century ago? Second, was the conception of the process of American urban economic development that lay behind the numbers a valid one? Third, what does this tell us about the utility of long-term projections for public policy?

The cryptic answers to the questions: first, the economic circumstances of the 1980's are quite different from the projected circumstances, almost entirely because of national (not regional) differences, including a significantly lower level of population and aggregate economic activity, and more rapid structural changes—mostly in the directions forecast in 1960. Second, as this implies, the conceptual underpinnings were, with only a few exceptions, spectacularly correct. Third, had public policymakers in the New York area accepted the forecasts as revealed truth and rigidly followed them in policy actions, they would have overbuilt some elements of public capital but otherwise would have done pretty much the right things. Had they accepted the underlying conception but recalibrated the projections periodically to reflect the national aggregates, even the over-capacity errors would have been avoided. This particular set of long-term projections, if no other, could have been useful for public policy, had attention been paid.

\*Urban Research Center, New York University, 4 Washington Square North, New York, NY 10003.

### I. The Nation and the Region

In the nine volumes of the study proper, there is relatively little explicit discussion of the national economy; the formal national projections that were an inescapable starting point for the regional analysis and projections appear in the technical supplement (Barbara Berman et al., 1960), complete with a disclaimer to the effect that the study essentially "borrowed" an existing model of the national economy for the 1955-85 period. That model, like *all* long-term forecasts of that era, projected a great deal of economic growth, to a very considerable extent stemming from the high current birth rates, which yielded high population growth rates. If age- and sex-specific labor force participation rates change only moderately and recent trends in labor productivity are extrapolated, the inevitable result is, at the cyclical peak that occurs at or near the target year, high growth rates in employment and output: in the study, an average annual growth rate of 4.3 percent in real *GNP* and of 2.4 percent in *GNP* per civilian employee over the thirty-year period (Vernon, Table A-1, p. 232).

There is a real problem in filling such large envelopes with output and employment by sector and industry. One cannot simply specify the rise of new, then-nonexistent industries (although one may be sure that some such industries will develop) or forecast the demise of industries that currently show all signs of health. Instead, the responsible course is to forecast that the sectoral composition of the national economy will change slowly, along the lines that then seem apparent. In the mid-1950's, that meant projecting continued growth in the main durable goods manufacturing industries, notably the auto industry, and an approximately stable share of manufacturing in total employment nationally. The results were plausible then, although they seem absurd today. For example, the background tables imply a projected increase in motor vehicle output from 1954 to 1981 (neither of them banner years for the industry) of close to 300 percent in constant dollars; the actual increase was about 100 percent. Most of the actual increase took the form of more value per unit; to realize the

Projected	1.7	1.4
Actual	1.5	0.9
Population		
Projected	1.8	1.5
Actual	1.3	0.5

*Note:* Projections are interpolations between the 1975 and 1985 figures in the appendix tables in Vernon with an adjustment for subsequent revisions in base-year employment data. Actual population figures from the *Census of Population: 1960*. The employment concept is "persons engaged in production," as in the National Income and Product Accounts, the source of the U.S. "actuals." Actual employment for the region based on *County Business Patterns*, supplemented by author's estimates for self-employment (based on the economic censuses) and Bureau of Labor Statistics data on government employment by county.

<sup>a</sup>Shown in percent: U.S. growth rates, 1955-81; New York region employment, 1956-81, and population, 1955-80.

projections, domestic auto output of about 12.5 million units, rather than 5.6 million, would have been needed in 1981.

In any event, the baby boom of the 1950's ended abruptly, and the national aggregates are well below those projected, employment less so than population, which is largely a consequence of there being so many fewer children in the mix today (see Table 1). The New York region had been expected to grow more slowly than the nation—what one would expect of mature regions—but in reality the growth was sharply below the national rates, not 80-odd percent of those rates. But to some extent even the accelerated relative regional declines can be attributed to the nationwide demographic factors. The study forecast that after 1980 the region would experience net out-migration

for the first time ever. Net out-migration appears to have started in the early 1970's; the early start seems partly due to the small numbers of potential *gross* in-migrants to be expected with a smaller national population, as well as the relative attractiveness of the region per se.

However, as Table 1 suggests, there was in fact some relative decline in the region's attractiveness, and more so as a place of residence than as the location of employment. The region's share of the national economy, as measured by employment, did decline somewhat more rapidly than the study had forecast. The region had 10.3 percent of U.S. employment in 1954 and the study (implicitly) projected that the share would fall to 9.1 percent by 1981; the actual result was 8.5 percent. The region's share of nonmanufacturing employment is now very close to the projected share, at 9.0 percent, which is a strong performance given the relative decline in population and the large extent to which local nonmanufacturing employment is local-population-serving. The region's relative weakness has been in manufacturing, in the study projected to decline, in its share of U.S. employment, from 11.6 percent in 1954 to 9.2 percent in 1981, but actually declining to 7.0 percent. As Table 2 shows, for the region as a whole, the actual absolute increase in non-manufacturing employment exceeded the projections, while there was a half-million decline in manufacturing employment instead of a projected 716,000 increase.

As suggested above, the fundamental error in the study's vision of industrial structure was the failure to forecast the sharp change in the role of manufacturing: manufacturing was projected to continue at about 28 percent of total employment from 1954 into the 1980's, but in fact declined to 21.5 percent by 1981. This error affected the region on the "share" as well as the "mix" side. In the study, the strongly growing manufacturing industries that had traditionally been heavily concentrated in the industrial Midwest were expected to grow mainly at dispersed locations, probably on the coasts, with the New York region actually increasing its share of employment in some of these industries, as

TABLE 2—PROJECTED AND ACTUAL EMPLOYMENT  
CHANGES IN NEW YORK REGION, 1956–81  
(IN THOUSANDS)

	Projected	Actual

Rest of Region		
Total	2,133	1,846
Manufacturing	667	– 37
Finance and business and professional services	513	837
Other industries	953	1,046

*Note:* See Table 1 for sources of data. Manufacturing excludes "administrative and auxiliary." "Finance and business and professional services" includes finance, insurance and real estate; administrative and auxiliary; radio and television broadcasting; and Standard Industrial Classification codes 73, 80, 81, 82, 84, 86, and 89.

had been the case with regard to the automobile industry in the years immediately preceding the study. In fact, there was much less total growth to be located and, with one major exception that is idiosyncratic to a single firm (Grumman and aerospace), the New York region did not gain from the diffusion of manufacturing away from the Great Lakes.

Manufacturing aside, the industrial structure errors in the projections were ones of degree, not kind: forecasting shifts in the right direction, but understating their magnitude, in particular underestimating the growth in jobs in government, finance, services and communications. The implicit 1981 national projection for services was about one-third below the level realized. Table 2 shows an underestimate of similar proportions for finance and business and professional services in the region. The study volume that focused on the shift-share analysis (Robert Lichtenberg, 1960) concluded that the region had a favorable mix that would be

offset by some competitive loss in share. The reality seems to be that the mix—the heavy concentration on finance and services—was even more favorable than had been forecast, but the loss of share also more pronounced; the job loss associated with the latter factor was compounded by the lesser growth in local population-serving jobs to yield the result shown in Table 2.

## II. Changes within the Region

For much of the study's audience, the aggregate size of the region was not of great moment: the important questions concerned what was likely to be going on within the region, and the study's findings on this score received considerable, often angry, attention. The technicians, however, were well aware that the intraregional projections were beset by serious methodological problems—for example, a miniature version of the shift-share analysis does not really work within regions, but there is no better alternative—and that the likelihood of serious, nonoffsetting errors was great. The test of the accuracy of these projections is not the actual numbers, but whether the vision was valid.

That vision sounds commonplace today, but it was hardly the conventional wisdom in 1960. New York City (except Staten Island, just about to be linked by bridge to the rest of the city) and the other old core cities would decline in population, the inner suburbs would grow moderately and the outer suburbs by very large numbers. The Manhattan central business district (*CBD*) would prosper mightily, and there would be substantial job growth everywhere outside the other parts of the core. The real difficulties would be in the vast expanses between the *CBD* (and the already-existing close-in slums) and the post-World War II suburban development, the sections Vernon called the "gray areas." In the late 1950's, these areas were occupied by manufacturing and other goods-handling activities that appeared to be viable and by what seemed stable middle- and working-class residential neighborhoods, to a considerable extent housing constructed during the great boom associated with the building of the subway network to Brooklyn, the

Bronx and Queens, from about 1910 through the 1930's. As Vernon pointed out, by 1985 that housing would be 50-or-more years old; it was built to not very high standards to begin with, at often very high densities (especially in the Bronx), and was likely to be seen by ordinary people in the 1980's as distinctly inferior to the characteristic suburban housing and neighborhood patterns developed in more recent decades. The neighborhoods might be an improvement for recent slum dwellers, but they would be everybody else's third choice, with vacancies and undermaintenance the result. The industrial areas also would be seen as inferior choices, inferior to newer industrial areas on the fringes of New York City (for example, near what is now Kennedy airport), to the outlying parts of the region and even to the industrial pockets within the *CBD*; the worst-faring industrial areas would be those in the smaller core cities of the region—Newark, Jersey City, Paterson, Bridgeport, and the like.

Those forecasts, denounced at the time, alas have proved to be, on the whole, optimistic. The smaller industrial cities have had massive losses in manufacturing employment and little if any offsetting increases in other types of employment. Within New York City, there was (between 1959 and 1981) a decline in manufacturing employment of roughly equal proportions—about 50 percent—in the *CBD* and in the outer boroughs. In the *CBD*, that job loss was made up by increases in service-exporting activities, with stability in total employment in local-population-serving activities. But in the Bronx, Brooklyn, and Queens, jobs in the local service activities declined and jobs in service-exporting activities are negligible, aside from the 50,000 or so in air transportation in Queens, with the upshot heavy losses in total employment (about 200,000 in Brooklyn alone), far heavier than the study projected. (For 1959 employment data, see Regional Plan Association, 1967.)

Similarly, the projections for population (and housing) in the gray areas were not dire enough. The study forecast that population in the three "old" boroughs of New York City (Manhattan, the Bronx, and Brooklyn) would decline considerably, but the decline

TABLE 3—PROJECTED AND ACTUAL POPULATION  
AND EMPLOYMENT CHANGES BY SECTOR OF REGION

<sup>a</sup>Nassau and Suffolk counties.

<sup>b</sup>Five counties in New York State and Fairfield County, Connecticut.

<sup>c</sup>Nine counties in northeast New Jersey.

was about 500,000 greater than forecast. The decline in household size was not sufficient to sustain housing demand outside of Manhattan, where the number of occupied housing units in 1980 was roughly equal to the 1960 level. However, in the Bronx and Brooklyn, there was a substantial decline—about 57,000—in housing units: housing investment in a few Manhattan-like pockets (Riverdale in the Bronx and the brownstone areas of Brooklyn) was far from enough to offset the massive abandonment in the South Bronx and eastern Brooklyn, in the former case including abandonment of what had been up-market middle-class housing built in the 1920's and 1930's.

Projected and actual changes in population and employment in the region outside New York City are shown in Table 3. The region's population and employment are somewhat more decentralized than had been projected, but the more interesting story seems to be the differences among the sectors, defined here roughly by compass directions. Long Island (in East Counties) actually attracted substantially more jobs and roughly the same number of residents as had been projected, but the other sectors grew much more slowly than projected. In part, the simple absence of population pressure

explains the results: with fewer people seeking places to live, one would expect less overspill from inner to outer areas. Moreover, restrictive land use controls should hold up better in the absence of such market-generated demand pressure: the study's projections implied that low-density zoning in outer areas, like northern Westchester and Connecticut, would not hold up at all.

The disparity between projected and actual is especially wide for the New Jersey sector (in West Counties), including both inner and outer sections. This seems related to the slow growth of manufacturing employment in general. The study's picture of the region shows New Jersey as having very large numbers of households supported by well-paid locally based blue-collar jobs in manufacturing. The counties to the north, especially Fairfield County in Connecticut, also attracted fewer manufacturing jobs than expected, but were more successful than New Jersey in attracting service-exporting activities.

### III. Projections, Perceptions, and Public Policy

On balance, therefore, it seems clear that the picture of the region in the early 1980's painted in the study was accurate in many respects, and would have been very accurate indeed had a smaller national population and the rapid shift away from manufacturing nationally been forecast. *Metropolis 1985* ends with a passage predicting that most of the region's residents would consider themselves reasonably well off in 1985, certainly as compared to 1960, while the planners and other experts would be highly dissatisfied. Surely, that is not the case: the "subjective reality," the perceptions of ordinary people, may be a lot worse, not much better, than the experts' perceptions of "objective reality." The old cities are worse off than expected by a wide margin; the public capital stock is in bad shape relative to the implicit forecasts in the study; and real income levels are a good deal lower than projected, to a considerable extent because of the macroeconomic events of the 1970's.

The New York study was not alone in seeming overly optimistic, after the event:

most long-term urban and regional studies from the late 1950's into the early 1970's, in all parts of the United States, share that characteristic, which seems to be largely responsible for the current shunning of long-term projections by urban analysts. However, the fact that the study was overly optimistic does not explain why its projections were largely ignored by policymakers in New York. Instead, the study's findings were rejected as too *pessimistic*. And so the city government spent a good deal of money pointlessly, in rehabilitating high-density housing in depopulating sections (rather than encouraging density-reducing land-use changes), in expanding subway service between Brooklyn and Manhattan, and in developing still-unused industrial parks to accommodate all that nonexistent manufacturing growth, to cite some examples. Moreover, the study implied that, in the core and the older suburbs, there would be need for an explicit strategy to replace infrastructure over time, quantified in a sequel to the study (Regional Plan Association, 1962). Historically, American state and local governments never explicitly replaced obsolete facilities, but instead did so as a by-product of building the new facilities necessary to accommodate population growth. Without such growth, replacement by inadvertence does not work, and did not work in the event.

No doubt, any long-term urban projections done today in the United States would be guarded indeed. But if the 1956-60 New

York study is any indication, intelligent, internally consistent projections that provide a coherent vision of the future of an urban region, whether that vision is upbeat or downbeat, can be of real use in public policy formation. They also can contribute to the development of analytic tools; no urban economists will allege that we have all that we need today.

# Long-Term Forecasts in International Economics

By WILLIAM R. CLINE\*

Eric Blair's forecast from the 1940's called for a 1984 international political economy with constant war between three global powers, designed to use up resources otherwise so abundant that the masses would be free to reflect on, and consequently depose, the bureaucratic elite (George Orwell, 1949). Orwell's forecast was wrong, although perhaps in part only because it was a self-negating prophecy: one that induces corrective measures.

Undoubtedly the most successful long-term economic forecast was Joseph's prediction to the Pharaoh of the fourteen-year agrarian business cycle. Others with less privileged information have fared less well. A founder of our own profession, Malthus, erroneously predicted long-term stagnation at the subsistence level, because he underestimated technical change (although for Sub-Saharan Africa and parts of South Asia, the Malthusian projection appears closer to the mark). This essay reviews long-term forecasts from the last several decades in the area of international economics, to see whether patterns can be distinguished in their success or failure.

## I. Secular Terms of Trade

In the 1940's and 1950's, some prominent economists maintained the thesis of a secular decline in the terms of trade for raw materials. Ragnar Nurkse (1944) spoke of "chronic" depression in terms of trade for agricultural goods, and Raul Prebisch (1959) built a theoretical justification for import-substituting industrialization around the concept that unfavorable demand elasticities would condemn producers of raw materials to continu-

ously declining terms of trade if they did not diversify toward industry.

The record has shown that terms of trade have fluctuated but not declined secularly. Declining terms of trade may be shown by selecting a high base period (such as the Korean War years) and a low terminal period (such as 1982); rising terms of trade may be shown by choosing a low base (the 1930's) and a high terminal period (1973-74). Technical change has lowered real prices of industrial goods, tending to offset lower income elasticities for raw materials. And there may be demand asymmetries that cause much sharper price increases for raw materials during boom years than the more gradual declines during years of weak international growth.

It is difficult to judge whether the long-term forecast of declining terms of trade has on balance done policy damage. It probably induced excessive and inefficient industrialization in developing countries. But some countries have succeeded in using the resulting industrial base for subsequent exports on an internationally competitive basis. Moreover, there is at least some degree of self-negation in the forecast: the fact that so many developing country planners accepted it meant less investment in raw materials exports, and thus a more favorable trend in terms of trade, than otherwise would have occurred.

## II. The Dollar Shortage

The record is less ambiguous on another popular long-term forecast of the early post-war period: that the dollar would be in chronic shortage. Defining the dollar shortage as a persistent tendency for the U.S. current account surplus to exceed its long-term capital outflow, Charles Kindleberger (1950) maintained that the shortage had existed since 1914 (except for the period of normalcy in 1922-28). He attributed the

\*Institute for International Economics, 11 Dupont Circle, NW, Washington, D.C., 20036.

problem primarily to a tendency toward secular stagnation in the United States relative to the rest of the world (p. 170).

Writing in 1956, Donald MacDougall (1957) acknowledged that there had been a "striking improvement" in the dollar shortage problem since 1946 as the result of increased production and currency devaluations in Europe. Yet he warned that dollar shortage was likely to return because of periodic U.S. recession, the tendency of other countries to live beyond their means as they sought to emulate U.S. living standards, and the structural advantages in U.S. trade in manufactures. His central forecast was that the rest of the world would run annual deficits with the United States, rising from \$ $\frac{1}{2}$  billion to \$4 billion over a decade. Because this trend would exhaust reserves in the rest of the world, MacDougall predicted a currency crisis in "five or six years at the latest" (pp. 325-26).

Even as authors were devising structural explanations for the dollar shortage, however, it was disappearing. After a large surplus on basic balance of payments (current account plus long-term capital and aid) of \$3.8 billion in 1947 (24 percent of merchandise exports), the balance shifted to a deficit of \$3.4 billion (34 percent of exports) during the Korean War year of 1950, the very year Kindleberger's book was published. Although the deficit then moderated, over the six-year period of MacDougall's predicted dollar shortage crisis (1957-62), the U.S. basic balance was in deficit by an average of \$2.3 billion (12 percent of exports; Walter Salant et al., 1963, pp. 6, 278-80). By the turn of the decade Robert Triffin (1960) was pointing out that the ongoing U.S. deficit would undermine the gold-exchange system by removing credibility of U.S. conversion of dollars into gold.

It is unlikely that predictions of chronic dollar shortage caused much policy mischief, however. The policy implications—increased U.S. economic assistance abroad, intensified efforts at export development in Europe, and so forth—can only be judged to have been salutary. But the predictions do illustrate one of the principal risks of long-term forecasts:

the tendency to project the conditions of the past into the distant future.

### III. Raw Materials Shortages

Richard Cooper (1975) has reviewed another long-term forecast: the projections in 1952 of the President's Materials Policy Commission (Paley Commission) on supply of raw materials to the U.S. economy, a report prompted by concern during Korean War scarcities. Cooper found that the Paley Commission projected excessive requirements of raw materials, with the mean forecast (among 24 mineral products) 46 percent above actual U.S. consumption in 1972. Moreover, the Paley Commission underpredicted U.S. growth at 2.8 percent annually instead of the actual 3.6 percent, for a total GNP shortfall of 20 percent by 1975, with underprediction evenly divided between population and productivity growth. Accordingly, its projections of raw materials use relative to GNP were even further off the mark. After finding that movements in relative prices could not explain the shortfall of minerals consumption from the forecast, Cooper concluded that the Paley Commission seriously underestimated technological change.

In one qualitative dimension, the Paley Commission was more successful: it correctly predicted that "It will pay the United States to import much more raw material in the future than in the past" (Vol. I, p. 12). Its projections expected the 1952 Korean War surge in import shares for copper, lead, and zinc to become permanent by 1975. But the authors missed the most important case of rising import dependence; they erroneously expected the nation still to be almost self-sufficient in oil by 1975, despite their unusually accurate forecast of total energy needs (Paley Commission, Vol. I, p. 22; Cooper, p. 241).

The Paley Commission projections illustrate two ways that projections can go wrong: inappropriate parameters in the projection model, and erroneous assumptions about the exogenous variables. (A third source of error would be inaccurate model

structure, as opposed to parameter values.) The Paley Commission's mistake on the exogenous variable, economic growth, was understandable following one decade of depression and another in which a common view was that peacetime demand would be slack. Less obvious, but actually more important for the error in the outcome, was parameter error. From Cooper's summary data, it may be inferred that the mean elasticity of minerals consumption with respect to *GNP* (among 24 products) was assumed to be 1.1, and the average 1.2 (excluding one outlier, manganese). In actual experience the elasticities turned out to be 0.74 and 0.85, respectively.

This divergence illustrates another aspect of long-term forecasting. It should be possible to inform the elements of the forecast by theory. In retrospect, theory could have suggested to the Paley Commission experts that technical change (as well as a secular rise in the share of services) would mean a less than unitary elasticity of raw materials inputs with respect to *GDP*. Although the Paley Commission stated that it had considered both factors (Vol. II, p. 112), its implicit elasticities indicate that insufficient weight was given to technological change in particular.

From a policy perspective, it is tempting to conclude that the projections were formulated to be on the safe side, in an environment of concern about security of access to raw materials. There is something to be said in favor of this direction of bias, especially if it leads to heightened awareness but not to costly and unnecessary remedial efforts.

#### IV. Balance of Payments

In 1963, the Brookings Institution published a projection of the U.S. balance of payments in 1968 (Salant et al.). The U.S. payments position and the dollar had come under pressure beginning in 1958, and the weak dollar was seen as a constraint on fiscal-monetary policies for full employment. An important policy question was whether the situation would be self-correcting. The projection effort was heroic, because the balance of payments concerns differences between trade (and financial) credits and debits, and even modest errors in the underly-

ing variables can yield large errors in the differences.

The Brookings team constructed a three-country model (United States, Europe, and rest of the world). The U.S. exports depended on Europe's income, its prices relative to U.S. export prices, and on rest of world export earnings. The U.S. imports depended on domestic income and prices relative to European export prices. The authors assumed slightly higher U.S. growth than for Europe (4.8 percent vs. 4.2 percent). But their critical assumption was that U.S. export prices would rise at only 0.5 percent, while Europe's would rise at 1.5 percent. Their rationale was that declining labor force growth in Europe would put upward pressure on wages (whether the guest workers were taken into account is unclear), and that European governments would not tolerate much unemployment to avoid inflation. Primarily because of improving U.S. price competitiveness, the authors concluded that the U.S. basic balance would shift from a deficit of \$0.85 billion in 1961 to a surplus of \$1.9 billion in 1968.

At least some commentators at the time suggested that by taking price increases as given for the United States but deriving higher price increases from expected wage increases in Europe, the authors were biasing the forecast toward optimism (John Williamson in Joint Economic Committee, 1963, pp. 851-59). But by far the major upset to the forecast was the Vietnam War, which caused a surge in U.S. demand and inflation. Actual export price increases averaged 2.0 percent for the United States and only 0.5 percent for Europe over 1963-68, reversing the projected relationship; and nominal U.S. *GNP* rose 46 percent instead of the projected 36 percent (International Monetary Fund, 1978). The actual outcome was a basic balance deficit of \$6.6 billion (Commerce Department, 1970, pp. 36-67), driven by large private and official long-term capital outflows. The projection's large surplus on goods and services (\$9.1 billion) failed to materialize (the actual figure was \$1.8 billion), leaving a large deficit instead of the projected basic balance surplus of \$1.9 billion (Salant et al., p. 216).

In an illustration of the difference between model error and error in assumptions on exogenous variables, Salant et al. acknowledged "...the possibility that the basic assumptions may be wrong—which is indeed a hazard, but one of forecasting, not of projecting..." (p. 227). And the underlying Brookings model appears not to have been seriously biased; for example, the model captured relatively greater response of imports to income in the United States than in Europe (p. 90), a stylized fact from later econometric work (Hendrik Houthakker and Stephen Magee, 1969). Nonetheless, it is perhaps too generous to grant total absolution for "forecasting" as opposed to "projection" (model as opposed to assumption) error, especially if the intended audience includes policymakers. It would have been more prudent to include as an alternative variant one in which U.S. inflation was significantly higher than that in Europe. Instead, the alternative considered permitted only modest changes (slightly lower U.S. growth, slower growth and lower inflation in Europe—but not faster U.S. export inflation than in the base case), yielding a small basic balance deficit for 1968 (\$0.6 billion).

In retrospect one also wonders whether what might be called the Norman Vincent Peale syndrome was involved: the temptation toward positive thinking in policy analysis. Rephrased as the Burt Lance principle ("if it ain't broke, don't fix it"), this approach is not necessarily wrong, and it may avoid costly measures that turn out to be unnecessary. But emphasizing the positive should be recognized as the opposite of a minimax strategy that errs in the direction of caution to avoid large damage. And to the extent that the Kennedy tax cut and, more seriously, the Johnson spending surge, were facilitated by upbeat forecasts on the balance of payments, the costs of error were potentially significant. In their defense, of course, the authors cannot be blamed for failing to predict the Vietnam War.

## V. Oil

In 1970, then-Secretary of Labor George Schultz headed a government study on the

issue of eliminating oil import quotas (Cabinet Task Force, 1970). The group favored import liberalization for economic reasons and argued that any security risks from greater reliance on imported oil were modest. The authors projected a decline in U.S. oil prices from the protected level of \$3.30 per barrel to the world price of \$2.00 (1969 dollars). They expected these real prices to hold through 1980, or even weaken as new production came in from the Alaskan North Slope. They projected that liberalization would increase the share of imports in 1980 U.S. oil consumption from one-fourth to one-half. But they anticipated little security difficulty because fully half of imports could come from Canada and Latin America, and only one-third would come from more unstable Arab states (with one-eighth from "reliable" Iran).

The task force did not err greatly in its volume estimate for U.S. oil consumption in 1980 (at 19.3 million barrels per day compared with 17.1 mbpd actual). Projected imports were somewhat further above actual (9.8 mbpd vs. 6.9), as some adjustment to sharply higher prices occurred. However, the Western Hemisphere turned out to supply only about one-fifth of imports (with Canadian supply far below projection), while Arab states provided nearly one-half (Commerce Department, 1983, pp. 528, 724–25).

Along with most other observers, the Cabinet Task Force failed to predict the OPEC price revolution. The actual 1980 price of \$34 per barrel was 8 times the projected level in real terms. The uncanny feature of this projection failure is that the task force was aware of the risk from OPEC price boosts, but rejected the risk as minor. The Cabinet Task Force study acknowledged:

Producing countries have sought and will doubtless continue to seek to increase their oil revenue by raising their taxes and royalties.... Whether they succeed in creating an effective price-raising cartel will, however, be largely independent of our import policy. ...[T]he world market seems likely to be more competitive in the future than in the past because the growing number and diversity of producing coun-

tries and companies make it even more difficult to organize and enforce a cartel. [p. 21]

Here the Norman Vincent Peale syndrome was, in retrospect, rampant. Moreover, the analytical framework of the authors based expected price on marginal cost of production and distribution, which they expected to be declining. Yet oil today is priced by the largest suppliers not at marginal production cost but at a reservation price, just as holders of gold bullion do not sell it for the marginal cost of removal from their vaults. Moreover, the task force seems to have been unaware that even as it was writing a historic change was taking place: U.S. proven reserves began to decline substantially (Commerce Department, 1983, p. 730). And the authors made the same mistake repeated frequently by others later in underestimating the cost of "backstop technology," anticipating that synthetic oil from shale could be produced at \$3.00 per barrel (p. 55).

Perhaps most seriously, the authors did not consider the interaction between their own policy recommendation and the likelihood of OPEC cartel action. Their projections indicated that, with liberalization, U.S. oil imports would surge from 2.5 mbpd in 1968 to 9.8 mbpd in 1980 (reaching 5 mbpd even without liberalization). Yet they treated the United States as a marginal importer and the world supply of oil as infinitely elastic. In fact, U.S. imports rose briskly to a peak of 8.5 mbpd in 1979. This increment amounted to perhaps one-fourth of OPEC export capacity. Rising U.S. imports almost certainly strengthened the demand conditions for the sharp OPEC price increases of 1973-74 and 1979-80. Moreover, although the authors were aware of another underpinning of potential OPEC power, low price elasticity of demand (the report used an elasticity of 0.1), they failed to draw the conclusion of considerable risk of a sharp price runup through coordinated OPEC action.

The Cabinet Task Force advocated eliminating oil import quotas because liberalization would save consumers \$5 billion annually (and provide net welfare gains of \$1.5 to \$2 billion annually). In the event, political

power of U.S. oil producers delayed liberalization until the mid-1970's. Actual costs to U.S. consumers from the increase in world oil prices by 1980 was approximately \$90 billion annually at 1969 prices.<sup>1</sup> Thus, if the probability was 5.6 percent (\$5 billion/\$90 billion) or higher that the elimination of U.S. oil import protection would ensure viability of the OPEC price revolution (by strengthening demand for OPEC exports), the recommendation to liberalize was a mistake. The odds are that this probability was at least this high, and in retrospect it would have been better to continue oil protection, although switching from a quota to a tariff would have transferred rents from foreign producers to the U.S. government.

## VI. Other Examples

In the early 1970's steel producers around the world adopted major expansion programs, encouraged by temporary shortages in the 1973 boom. Within a decade there was massive excess capacity in world steel and the principal policy question was how to phase down production capacity. In the late 1970's, developing countries borrowed, and foreign banks lent, heavily on the basis of the implicit long-term forecast that the real interest rate would remain low or negative and export growth would remain rapid. By 1982 the U.S. macro policy mix and global recession thwarted both predictions and the debt crisis resulted.

In 1978, the World Bank issued its first *World Development Report* (World Bank 1978). The authors predicted that, after disappointing growth of 2.8 percent annually in 1970-75, the industrial countries would grow at 4.2 percent in 1975-85. The developing countries, which had managed to continue high growth of 5.9 percent in 1970-75 (in part by borrowing in response to the oil shock), would continue their growth at 5.7 percent in 1975-85 (p. 27). The actual record of growth in 1975-84 turned out to be 2.9

<sup>1</sup>Applying the GDP Deflator to \$34 per barrel, subtracting \$3.30 per barrel as the comparison price, and multiplying by 19 mbpd projected consumption.

percent annually for industrial countries and 3.2 percent for developing countries (IMF, 1984, pp. 169–70). The report did not anticipate the second oil shock, the concerted contractionary policy response to it, and the worst global recession since the 1930s.

### VII. Lessons

A broad implication of this review is that long-term forecasts are rarely right. One might have expected that by random chance at least one-half of the forecasts would turn out to be correct in at least qualitative terms. Yet the sample here is not (intentionally) biased toward historical mistakes.<sup>2</sup> It is possible that an asymmetry exists between successful and unsuccessful long-term forecasts. Both types come in two varieties: adverse and favorable. A successful (accurate) forecast that is adverse may become self-negating as public and private actors take corrective measures; one that is favorable may generate market responses (to profit opportunities) that also reduce its *ex post* validity. There are no corresponding mechanisms for turning bad forecasts into good ones, except random chance. A simpler interpretation, of course, is that long-term forecasts are usually wrong because they are difficult to make. Despite their difficulty, they cannot be avoided; anyone planning for retirement at least implicitly makes them, corporations need them, and governments must make choices that require them.

Long-term forecasters should avoid the tendency merely to extrapolate past experience, a pattern present in nearly all of the forecasts considered here. Attention to likely structural changes in the future, especially technological change, can help avoid this pitfall. In modeling terms, care must be used

not only in model structure, but also in changes from past trends with regard to assumptions on future values of exogenous variables and choice of parameter values. Where possible, theory should be coupled with empirical experience for improved results in all three areas.

Forecasters can take some solace from the likelihood that, in a good forecast, the basic outcome may be predicted correctly even if not all of the underlying variables turn out as expected. If errors are randomly distributed, the chances are that the value of the dependent variable in a multivariate model will not be far wrong, because departures in one direction for some exogenous variables will tend to be offset by departures in the other direction for others (see my 1984 study, p. 169). Finally, policy forecasting should avoid at least two temptations: to corroborate the view of the established regime, and to err systematically on the side of optimism. Ideally, sensitivity analysis should be included, with an assessment of the probabilities of alternative outcomes, and attention to the policy costs of premising action on the wrong one.

# The Economic Thought of George Orwell

By JENNIFER ROBACK\*

Despite the volumes that have been written about George Orwell during this past year of 1984, virtually no one has commented on the economic assumptions implicit in his work. Yet understanding the economics in Orwell's vision of hell is necessary if we are to fully appreciate the horror of that vision. Orwell believed that socialism led to totalitarianism; indeed, that is the chief message of Orwell's 1949 classic. But he also believed that capitalism led to breadlines and poverty. This combination of beliefs led him to that profoundly disturbing view he described so vividly in *1984*.

But probably the most remarkable aspect of Orwell's economic thought is that he said so little explicitly on the subject. He wrote literally volumes of social and political commentary, with an economic worldview implicit in every line. Yet, explicit discussion of economics is limited to a few pages in *1984* and offhand comments scattered throughout his book reviews and essays. The statements that he did make suggest that his economic ideas were obviously influenced by Marxist theory, but were not revolutionary. That is, his views were quite conventional for his time.

His views about technology are quite another matter. Orwell was not opposed to or in favor of technology per se. His primary concern was over who would control technology. Would new technologies be widely available for personal use or would they be centrally controlled? In this area Orwell was a decentralist, radical for his time and for ours.

## I. Orwell's Economics

The first thing to be said about Orwell the economist is that he was a socialist. He be-

lieved that income inequality was an inherent feature of capitalism, and this was his primary motivation for becoming a socialist. "I became pro-Socialist more out of disgust with the way the poorer section of the industrial workers were oppressed and neglected than out of any theoretical admiration for a planned society."<sup>1</sup>

Orwell believed that overproduction was a necessary feature of industrial capitalism. This creates a surplus of goods which workers would not be able to afford and which capitalists could not consume. This in turn requires either some means of disposing of the surplus production or a periodic crash of the economic system.

Ever since the end of the nineteenth century, the problem of what to do with the surplus of consumption goods has been latent in industrial society. ...[D]uring the final phase of capitalism roughly between 1920 and 1940[,] [t]he economy of many countries was allowed to stagnate, land went out of cultivation, capital equipment was not added to, great blocks of the population were prevented from working and kept half alive by State charity...the problem was how to keep the wheels of industry turning without increasing the real wealth of the world. Goods must be produced, but they need not be distributed.<sup>2</sup>

Orwell also believed that capitalism had strong tendencies toward monopoly and increased concentration. This exacerbates the overproduction problem. Capital becomes

<sup>1</sup>See, Sonia Orwell and Ian Argus, *The Collected Essays*, ..., Vol. III, p. 403. All quotations in the text are from the *Essays* unless otherwise noted.

<sup>2</sup>Orwell (1983, pp. 155-57). This passage comes from the "forbidden book" of Emmanuel Goldstein. In the context of the story, *The Book* is clearly speaking for Orwell when it describes the capitalist system that formerly existed in Oceania.

\*Assistant Professor of Economics, Yale University, New Haven, CT 06520.

concentrated in fewer and fewer hands, hence the output is owned by a smaller number of people, who are less likely to be able to consume all of it: "The notion that industrialism must end in monopoly, and that monopoly must imply tyranny, is not a startling one" (*Essays*, Vol. IV, p. 163).

These ideas, overproduction and periodic crashes, the tendency toward monopoly, and income inequality are traditional socialist concerns. And on the basis of these beliefs and concerns, Orwell was a socialist. This general worldview was widely held by British intellectuals of Orwell's time. Indeed, the period after World War I was one of the highwater marks for socialism, both in Britain and in the United States. It is in this sense that Orwell's economic views can be described as quite conventional for his time.

However, Orwell was no ordinary socialist, once we look beyond his economics. In particular, Orwell was not a utopian socialist, as were so many of his contemporaries. He believed that socialism had strong tendencies toward centralization and that centralization in turn had strong tendencies toward totalitarianism.

This view was based on two things. The first was Orwell's observation that the Soviet Union, on which so many English socialists placed their hopes, was unmistakably totalitarian. Orwell expressed this opinion on many occasions and in many ways.

Since 1930 I had seen little evidence that the USSR was progressing towards anything that one could truly call Socialism. On the contrary, I was struck by clear signs of its transformation into a hierarchial society, in which the rulers have no more reason to given up their power than any other ruling class.

[*Essays*, Vol. III, p. 405]

Orwell was disgusted with English socialists, because they failed to point out the tyranny which existed in the Soviet Union. In fact, they seemed to him to feel obligated to defend every Soviet action. In Orwell's opinion, these Soviet apologetics were destroying the chances of true socialism ever being established in Great Britain.

It was only *after* the Soviet regime became unmistakably totalitarian that English intellectuals, in large numbers, began to show an interest in it.

[*Essays*, Vol. IV, p. 179]

[N]othing has contributed so much to the corruption of the original idea of Socialism as the belief that Russian is a Socialist country and that every act of its rulers must be excused, if not imitated.

And so for the past ten years I have been convinced that the destruction of the Soviet myth was essential if we wanted a revival of the Socialist movement.

[*Essays*, Vol. III, p. 405]

The other factor which led Orwell to worry about socialist totalitarianism is the obvious fact that central economic planning requires someone to have the power to make and enforce the central economic plan. That person or group of people will have enormous power over their fellow citizens. Such power can be used for vicious political ends, as in Stalin's Russian or in Orwell's Oceania, as well as for the benevolent purposes of economic planning: "[I]t has always been obvious that a planned and centralised society is liable to develop into an oligarchy or a dictatorship" (*Essays*, Vol. IV, p. 163). And Orwell did believe that economic planning was a central feature of the more efficient and just economic system that he envisioned and called socialism.

So Orwell thought that capitalism was unjust and inefficient, but that socialism, the best alternative he could come up with, would lead toward totalitarianism. He expresses this view most starkly in his book review of Frederick von Hayek's *The Road to Serfdom*: "Capitalism leads to dole queues, the scramble for markets, and war. Collectivism leads to concentration camps, leader worship, and war" (*Essays*, Vol. III, p. 119).

Thus Orwell's view of society's future was far more pessimistic than those of his contemporaries, and at a much deeper level. He sees no solution to the dilemma. Although this troubled him greatly, it did not seem to lead him to reexamine either his view of capitalism or of socialism. In economists'

jargon, no equilibrium existed in Orwell's model of the world. Capitalism was unstable in one direction while socialism was unstable in another. Orwell never saw a way out and spent a lifetime living with the belief that civilization was on its last legs. "When one considers how things have gone since 1930 or thereabouts, it is not easy to believe in the survival of civilisation" (*Essays*, Vol. IV, p. 248).

## II. Orwell's Views on Technology

Orwell's views on socialism and totalitarianism didn't win him many friends among intellectuals of his era. His views on technology probably wouldn't win him many friends today, and would probably surprise the many commentators who have claimed that *1984* is an attack on technology.<sup>3</sup> One of Orwell's prime beliefs was that machines have both increased the standard of living of the average man and have relieved him from all sorts of menial drudgery:

From the moment when the machine first made its appearance it was clear to all thinking people that the need for human drudgery, and therefore to a great extent for human inequality, had disappeared. ... And in fact, ... the machine did raise the living standards of the average human being very greatly over a period of about fifty years at the end of the nineteenth and the beginning of the twentieth centuries.

[1984, p. 156]

Thus, Orwell, like many other socialists of his day,<sup>4</sup> thought that improved technology provided the means for ever increasing standards of living.

Surely his most startling view on technology is that all technology should be widely available to the ordinary citizen and not controlled by a central government authority. In a remarkable article called "You and

the Atom Bomb," written in 1945, he applies this line of reasoning even to atomic weapons.

Some months ago, when the bomb was still only a rumour, there was a widespread belief that splitting the atom was merely a problem for the physicists, and that when they had solved it a new and devastating weapon would be within reach of almost everybody. (At any moment, so the rumour went, some lonely lunatic in a laboratory might blow civilisation to smithereens, as easily as touching off a firework.)

Had that been true, the whole trend of history would have been abruptly altered. The distinction between great states and small states would have been wiped out, and the power of the State over the individual would have been greatly weakened....

...[T]hough I have no doubt exceptions can be brought forward, I think the following rule would be found generally true: that in ages in which the dominant weapon is cheap and simple, the common people will have a chance....

Had the atomic bomb turned out to be something as cheap and easily manufactured as a bicycle or an alarm clock, it might well have plunged us back into barbarism, but it might, on the other hand, have meant the end of national sovereignty and of the highly-centralised police state.

[*Essays*, Vol. IV, pp. 7-9]

One can't help wondering what Orwell would have thought about gun control ordinances.

Thus, much of the commentary about Orwell this past year has simply been wrong. The book *1984* is not about television screens and computers, as we have so often been told; it is a book about totalitarianism and socialism. It is a book, not so much written as a prophecy, but as an alarm bell, rung by a man who hardly dared to hope that anyone would answer it. *1984* is a book born of a profoundly pessimistic worldview. I now turn to the world in which Orwell lived and which created this worldview.

<sup>3</sup>See, for example, the essays in Irving Howe (1983).

<sup>4</sup>Oscar Wilde, for example, held this view even more strongly than Orwell. See Orwell's review of *The Soul of Man under Socialism* in *Essays*, Vol. IV., pp. 426-28.

### III. Orwell's Era and Its Mood

Orwell was born in England in 1903 and died in 1950. He lived through one of the most calamitous periods of modern history. As a teenager, he saw World War I; as a young man, he lived through the depression; and in his prime, he experienced World War II. He saw the rise of Bolshevism in Russia; he watched as the promise of communism was betrayed by Stalin. He observed Hitler and the rise of fascism in Europe. He personally fought in the Spanish Civil War against the fascism of Franco. While he was there, he saw how the Soviet-backed Communists fought their anarchist and socialist allies as much as they did their fascist opponents. He foresaw the fall of Spain to fascism (see Orwell, 1980).

The early twentieth century, then, was an era of despair. The generation that fought World War I was often described as the "Lost Generation," partly because so few of them returned, and partly because those who did return were so broken in spirit. Indeed, World War I was widely regarded as the end of civilization. Orwell some years later captured this mood when he wrote:

Many people have remarked nostalgically on the fact that before 1914 you could travel to any country in the world, except perhaps Russia, without a passport. ... Clearly, that is not the kind of social atmosphere that we shall ever see again, and when Sir Osbert Sitwell writes of "before 1914" with open regret, his emotion can hardly be called reactionary. [*Essays*, Vol. IV, p. 443]

Even if the war was not the end of civilization, it certainly was the death knell of classical liberalism, and its optimistic notions of economic freedom and limited government. The Great War was widely regarded as a failure of classical liberalism, and only partly because the Liberal Party was in power when England entered the war. The mere fact of the war itself cast serious doubt on the classical liberal view that free trade and free migration were sufficient to preserve world peace. This view had been a cardinal

tenet of British liberalism in the nineteenth century.

If the Great War was a severe blow to classical liberal politics, the Great Depression was an even more severe blow to classical liberal economics. It was widely believed that the depression was the result of massive market failure, and that the *laissez-faire* policies of the liberals were obsolete. But abandoning liberal economic policies also meant abandoning much of the optimism of liberalism. The idea of an Invisible Hand is itself profoundly optimistic. It says that the common good is being served, even when it is not apparent how. Orwell himself recognized the optimism of the liberals in the following passage: "[T]he Left has inherited from Liberalism certain distinctly questionable beliefs, such as the belief that the truth will prevail and persecution defeats itself, or that man is naturally good and is only corrupted by his environment" (*Essays*, Vol. IV, p. 410).

But all of these notions of economic liberalism went decidedly out of fashion during the early years of Orwell's life. To be sure, socialist arguments against liberalism had been around for some time. But by the middle of Orwell's life, the socialists dominated both the intellectual life and the policymaking process in Great Britain.

This is the sense in which Orwell was truly a child of his era. He shared the pessimism of the Lost Generation. Like his contemporaries, he took for granted that capitalism was dead. This explains the almost offhand nature of many of his comments about economics. "Everyone knew" that capitalism was dead. A detailed defense of that position was not necessary. What was necessary was to find alternatives, no matter how radical, to capitalism. Many people believed that "the Soviet Experiment" was that alternative. But, as we have seen, Orwell had serious reservations about that road to socialism.

### IV. Flaws in Orwell's Economic Vision

It is easy to see how Orwell came to believe that capitalism leads to breadlines and socialism leads to totalitarianism. Both of these ideas seemed to be borne out by ob-

servation of his immediate world. The problem with Orwell's economic analysis is that he accepted the interpretation of the Great Depression that was standard at his time, but which has since undergone serious revision. He also had no understanding of the difficulties of scientific socialism, again a problem which has been widely discussed since his time.

In Orwell's time, the Great Depression was widely regarded as proof of the instability of *laissez-faire* policies. Indeed, this interpretation gave rise to the Keynesian Revolution which prescribed more active intervention by the central government into the management of the economy. But this view has been widely challenged in the intervening years. Milton Friedman and Anna Schwartz's critique (1963) of activist policy included a reinterpretation of the causes of the Great Depression. His view is that, far from being a failure of *laissez-faire*, the depression was a failure of intervention by the Federal Reserve. Now this view is not universally accepted, but then again, neither is the old view universally accepted. Today at least there is some challenge or alternative to the view which Orwell and his contemporaries took for granted. One must at least consider the possibility that ill-conceived intervention contributed to the depression.

But it would be asking a great deal of Orwell to expect him to anticipate this neo-classical critique. A greater failure is that he had no understanding of the difficulties of "scientific socialism," as it was called. A great debate raged during the 1920's and 1930's on the possibility of industrial socialism.<sup>5</sup> One school of thought, led by Oskar Lange and Abba Lerner, argued that central planning could be done efficiently, provided that the planners used marginal cost shadow pricing to simulate market pricing. The op-

posing school of thought, led by Ludwig von Mises and the Austrians, argued that the advocates of marginal cost pricing were overlooking the essential difficulty of central planning. The Austrians argued that in the absence of a market process, there is no reliable way to discover marginal costs and efficient levels of output and efficient methods of production. For a review of this debate, see Trygve Hoff (1981).

This criticism has been repeated in many forms for many problems. Economists often criticize both "industrial policy" and "comparable worth" on these grounds. How can government industrial policy choose the potential "winners and losers" in the world marketplace in the absence of the actual competitive process? How can the judiciary determine jobs of comparable value without reference to market wages? The fact that these proposals continue to emerge and that some economists support them demonstrates that opinion on these matters is by no means uniform, even among economists. However, it is naive to assume, as Orwell seems to have, that planning an economy is a straightforward extension of the exercise of planning a family shopping list. He seems to have thought that if one activity requires planning in order to be successful, then surely the other does as well.

The essential missing link in Orwell's understanding of economics is that he had no notion of the price system as a coordination mechanism. Price changes convey information to all of the diverse economic agents, and this information allows them to coordinate their plans. And based on this minimal information, the agents make their own plans, and take their own actions. The adjustments of the price system make it possible for all of those plans to be coordinated. This is the basic meaning of the concept of equilibrium. That is why central planning is not simply individual planning on a larger scale. The central planner must coordinate the plans of the many individuals, a job which the market economy leaves to the Invisible Hand.

Orwell seemed to have no appreciation of the magnitude of the coordination problem that the price system attempts to solve. In short, Orwell had no notion of what is

<sup>5</sup>The following passage suggests that Orwell had some knowledge of this debate: "I am well aware that it is now the fashion to deny that Socialism has anything to do with equality. In every country in the world a huge tribe of party-hacks and sleek little professors are busy 'proving' that Socialism means no more than a planned state-capitalism with the grabmotive left intact" (1980, p. 104).

sometimes called spontaneous order in economics. If there is no explicit planner, there must be no plan. And without a plan, there must be no order.

#### V. Conclusion

These then are the economic ideas which led Orwell to believe that capitalism was doomed: a particular interpretation of the Great Depression, and no concept of spontaneous order or market process. It is interesting to speculate about how Orwell's thought might have developed had he not died prematurely in 1950 at the age of 47. Had he observed the problems of British socialism and of the major centrally planned economies, he may have revised his estimate of the ease and desirability of central economic planning. He had always had a distinct mistrust of the central political power inherent in socialism. Perhaps if he had observed some of the economic difficulties of socialism, he may have rejected it outright, rather than trying to reform it. Of course, he may have just hated socialism along with capitalism. If so, this would have added to the profound

pessimism which he felt during all of his short life. He expressed it rather poetically in a letter to his friend Arthur Koestler in the spring of 1946, "Each winter I find it harder and harder to believe that spring will actually come" (*Essays*, Vol. IV, p. 127).

## Hamlet without the Prince: Cambridge Macroeconomics without Money

By J. A. KREGEL\*

Keynes' *General Theory* was exclusively concerned with a monetary economy in which changing beliefs about the future influence the quantity of employment. Yet money plays no more than a perfunctory role in the Cambridge theories of growth, capital, and distribution developed after Keynes. This essay attempts to explain this paradox with reference to the relation between Keynes' monetary revolution and the value theory revolution which simultaneously occurred in Cambridge in the 1930's.

### I. The Instability of Credit

The *General Theory* has often been described as provoked by the Slump, yet F. Vicarelli (1984) argues that it also represents the theoretical formulation of reflection on the nature of capitalism begun in the 1920's. Hayek describes this period: "We all held similar views...more fully elaborated by R. G. Hawtrey who was all the time talking about the inherent 'instability of credit'" (in Milton Friedman, 1969, p. 88n). Indeed R. G. Hawtrey's 1913 *Good and Bad Trade* foreshadowed a monetary theory of effective demand:

[T]he manufacturer's efforts in producing...goods depends upon there being an effective demand for them.... It is only because the dealer anticipates... this effective demand...that he gives the manufacturer the order.... The manufacturer...accepting the order, and the banker...discounting the bill,

are both endorsing the opinion of the dealer. The whole transaction is based ultimately on an expectation of a future demand, which must be more or less speculative. [p. 78]

The impact of money on the level of activity inspired not only Hayek and Keynes, but Robertson, Schumpeter, Pigou, Cassel, and others. These economists, to whom Keynes addressed his 1923 *Tract on Monetary Reform*, all implicitly accepted the quantity theory of money; open rejection of this common analytical framework in the 1930 *Treatise on Money* made communication with his contemporaries difficult, and Keynes had to look elsewhere for sympathetic criticism.

### II. Cambridge Value Theory in the 1930's

At the same time, a group of young Cambridge economists, Kahn and Joan and Austin Robinson, were extending Sraffa's 1926 criticisms of Marshall's theory of value to produce the "Imperfect Competition Revolution." It was among these economists, and others involved in developing imperfect competition such as Harrod, Kaldor, and Kalecki, that Keynes' ideas created interest. They did not, however, have first-hand experience of the earlier "monetary" debates, indeed, for many skepticism of the quantity theory (see R. F. Kahn, 1984, p. 52) deterred them from the study of monetary factors which had inspired Keynes' generation. Thus the Cambridge economists who formed the "Circus," and others such as Harrod, who played a central role in discussing and elaborating the *General Theory*, were all involved in the value theory revolution before they joined Keynes' monetary revolution. It is not surprising that they should have perceived a relationship, although Keynes believed that developments

<sup>†</sup>Discussants: Donald Harris, Stanford University; Mark Kuperberg, Swarthmore College.

\*Professor of Economics, University of Groningen, The Netherlands.

in value theory were independent of his own pursuits.

The *Treatise* replaced the equation of exchange as determinant of the price level with the "fundamental equations" which combined Marshall's short-period supply and demand factors in a sort of reduced-form equation representing the composition of expenditure relative to the composition of output. Money retained only indirect influence on prices via the influence of the rate of interest on the divergence of saving and investment producing "windfall profits." Here Keynes followed Wicksell and called "natural" the interest rate that produced price equilibrium. Keynes' new interlocutors were to draw on their value theory expertise to provide two crucial elements for the transformation of the "fundamental equations" into the analytical framework of the *General Theory*: Kahn's analysis of short-period supply and Sraffa's conception of commodity rates of interest.

#### A. Kahn's Short-Period Analysis

It was Mr Kahn [in his multiplier article] who first attacked the relation of the general level of prices to wages in the same way as that in which that of particular prices had always been handled, namely as a problem of demand and supply in the short period rather than as a result to be derived from monetary factors.

[Keynes, 1939, in 1973, p. 400, fn. 1]

Kahn also convinced Keynes that the price of investment goods should be handled in an analogous fashion, thus separating the combined supply and demand aspects of the fundamental equations which opened the way to an aggregate demand function representing consumption expenditures (from wages) and investment expenditures (from profits) and an aggregate supply function to determine the "aggregate" price level as an application of his value theory investigations into "short-period supply" to Keynes' monetary studies. While others, such as Hicks, were applying value theory to the demand for money, in Cambridge it was being applied to the "fundamental equations."

Indeed, Kahn (p. 99) considers his greatest contribution to Keynes' theory as the demonstration that investment generates the savings required to finance it, which convinced Keynes to adopt savings-investment equality. This eliminated the second term of the fundamental equations and facilitated application of aggregate supply and demand analysis, but it also eliminated money from even an indirect role via interest rates on prices. Sraffa was to provide the new role for money and the rate of interest.

#### B. Sraffa's Commodity Rates of Interest

In his 1932 review of Hayek's *Prices and Production*, Sraffa formulated commodity rates of interest to criticize Hayek's use of Wicksellian "natural" rates of interest (which had equated saving and investment in the *Treatise*). Hayek's theory suggested that if the presence of money was "neutral," the natural rate of interest would equate investment to full employment saving and Say's Law would necessarily prevail.

Hayek's "neutrality" required the money rate of interest equal the "equilibrium" (natural) interest rate so that money savings should buy the same amount of producers' goods as if the supply and demand for capital met in "their natural form." Sraffa pointed out that natural rates exist implicitly for every commodity, and explicitly whenever there is a forward market. These rates will be uniform in an equilibrium in which "the spot and forward price coincide" for each commodity. But when savings, whether in money or natural form, are positive there may be as many natural rates as there are commodities for:

[U]nder free competition this divergence of rates is as essential to... transition as is the divergence of prices from the costs of production; it is, in fact, another aspect of the same thing.... [This] applies as much to an increase in saving, which Dr. Hayek regards as equivalent to a shift in demand from consumers' to producers' goods, as to changes in the demand for or the supply of any other commodity.

[1932, pp. 50-51]

Since it is the competitive price adjustment process, not the nonneutrality of money which causes divergence of individual commodity rates and these from the money rate, neutrality cannot be defined in the conditions Hayek proposed.

Sraffa's criticism suggested that the influence of money was not via interest rate effects on saving and investment, but via the divergence of commodity rates which was just "another aspect" of the divergence of demand prices from supply prices leading to production decisions for consumption or investment goods. The rate of interest provided a parallel representation at the level of individual production decisions for the divergence of aggregate demand and supply prices which was emerging from the elaboration of the fundamental equations, but one in which money was clearly central to the determination of the expenditure decisions which brought changes in production and employment.

### III. Interest Rate Parity and Liquidity Preference

In Keynes' monetary economy, money offered an alternative to investment in other durables; it thus required a comparable definition of its rate of interest in terms of spot and forward prices. Keynes thus defined the money rate of interest as "nothing more than the percentage excess of a sum of money contracted for forward delivery, e.g. a year hence, over what we may call the 'spot' or cash price of the sum thus contracted for forward delivery" (1973, p. 222). This change in the way money entered Keynes' analysis allowed an analogy with the *Tract's* "interest rate theorem" (see my 1982 article) to explain decisions to take positions in durables (including money) since every durable has spot and forward prices in terms of itself as numeraire giving its "commodity" or "own-rate of own interest": "just as there are differing commodity-rates of interest at any time, so also exchange dealers are familiar with the fact that the rate of interest is not even the same in terms of two different moneys..." (Keynes, 1973, p. 224).

In the exchange market, equilibrium is achieved when the forward discount or pre-

mium reaches equality with the interest differential. Just as the forward discount in the *Tract* measured the market's "preference" for holding that currency, Keynes now argued that the market's preference for holding money was also measured by the discount of future over spot money in terms of money: the rate of interest. Equilibrium was thus defined by the equalization of the relative advantages of taking positions in durable assets, that is, when all the own-rates evaluated in money were equal to the own-rate on money.

In this way Keynes gave expression to the way "changing views about the future are capable of influencing the quantity of employment and not merely its direction" (1973, p. vii), for every decision to purchase (invest in) a durable at prevailing spot prices depends on expectations of future conditions as expressed in future prices: the relation of spot to forward prices or supply and demand prices determines rates of return on investment in durable goods or their marginal efficiencies, while liquidity preference sets the spot and forward price of money, the rate of interest. Marginal efficiencies and liquidity preference thus reflect views of the future or the state of general expectation. The composition of asset holdings and overall expenditure decisions were thus directly influenced by changing views of the future. Since each individual had to reach his or her own view on the relation between present and future prices to determine the investment and expenditure strategy which maximized expected rates of return, decisions to buy investment goods or to hold money would be characterized by diversity of view as to expected rates. Equilibrium would be established when market prices for any activity produced a balance of divergent expectations. In such conditions, as Shackle has stressed, actual events may disappoint every agent's expectations, forcing frequent reconsideration of position and making decisions to invest liable to constant fluctuation. It was only possible to discuss equilibrium on the assumption of a given state of general expectation in which an increase in investment, or shifts between activities, eliminates discrepancies in own-rates evaluated in money

(marginal efficiencies) by means of adjustment in spot prices, current production (i.e., net investment), or the degree of liquidity, depending on the type of market and type of activity (see M. Tonveronachi, 1983, pp. 167-68).

Changes in expected future conditions thus influence divergences in marginal efficiencies which reflect differences between costs of production and prices which initiate expenditure decisions and affect both future supply and prices. Adjustment continues until marginal efficiencies and the money rate of interest are brought into equilibrium. Equilibrium could thus be represented in the aggregate in terms of effective demand equating aggregate supply price or on the individual level as uniformity of own-rates given by spot and forward prices of durables.

Further analysis of the nature of money and the behavior of liquidity preference was necessary to determine whether the equilibrium thus achieved was durable at less than full employment, for if money rates could be brought to a sufficiently low level to lead individuals to spend all of their income on current production, then full employment was the only stable position. Keynes suggested that since interest rates represented expectations of future rates, such a policy would only succeed if individuals could be convinced that reductions in money rates would not be reversed. His simple formula showing how capital loss offsets yield for smaller rises in interest the lower the prevailing rate (1973, p. 202) suggested that healthy skepticism (reinforced by the appearance of "semi-inflation" if money wages progressed more rapidly than productivity as expenditure increased) would lead rational investors to increase liquidity preference, causing the money rate to be the one to "decline most slowly as the stock of assets in general increases" (1973, p. 229), producing equilibrium (and confirming the skeptics' opinions) before full employment is reached.

But orthodox theory had argued that even if increased hoarding reduced the demand for goods, this would only change the direction, not the amount, of employment if money were produced by labor. Keynes' "essential properties of money" rather than the

liquidity trap are meant to meet this point; if the elasticities of production and substitution of money are negligible then the demand for money is not a demand for goods and money provides a "sink" for purchasing power.

#### IV. Own-Rates and Aggregate Supply and Demand

Discussion of a monetary economy characterized by money bearing these essential properties formed the introduction to early drafts of the *General Theory*, reflecting Keynes' announcement of a "Monetary Theory of Production" in the Spiethoff *Festschrift*, but was to be replaced by the short-period equality of aggregate supply and demand price representing the principle of effective demand. Money appears as an integral part of the discussion of the determinants of investment, reflecting Keynes' move towards the identification of investment as the *causa causans* in determining output and employment; while money loses pride of place, it gained in importance, providing the very basis for the explanation of the inherent instability of investment in a capitalist economy, and the explanation for persistent unemployment equilibrium by means of the "essential properties." The final title announces a general theory in which "Employment" is determined by "Interest and Money."

Thus the two influences from the value theory revolution provided parallel frameworks for presentation of Keynes' revolution in monetary theory; the "Marshallian" analysis in terms of aggregate short-period supply and demand prices took on the more visible role in chapter 3, representing the changed role of money as the basic determinant of individual investment decisions determining asset prices reflecting liquidity preference, and explaining unemployment equilibrium.

Hicks was clearly more impressed by the aggregate supply and demand framework, but proposed his own Walrasian basis by aggregating a general equilibrium system into "bundles" representing three "market" equilibria in which equality of the natural and market rate of interest replaces that of "aggregate" supply and demand prices of the

principle of effective demand. This formulation placed money within the Walrasian framework and replaced Keynes' discussions of money and investment decisions with a constraint on the demand for money so as to produce a horizontal "Keynesian" range to the *LM* curve where a stable interest rate (the only price) also implied fixed wages and prices. Keynes vigorously denied such a relation and instead suggested that: "the difference between myself and the classicals lies in the fact that they regard the rate of interest as a non-monetary phenomenon" (1973b, p. 80). Keynes felt that his analysis of the effect of money and interest on investment had been overlooked because readers had placed undue emphasis on the difference between expected and actual demand. He repeats the point made to Hicks in a series of articles published in 1937, arguing that in his theory money was a "real" factor which could affect relative money prices and outputs in the long period as well as the short, while in difference to the theories of Wicksell and Hayek, the rate of interest was a purely monetary factor, independent of any real or natural forces:

Put shortly, the orthodox theory maintains that the forces which determine the common value of the marginal efficiency of various assets are independent of money, which has...no autonomous influence, and that prices move until the marginal efficiency of money, i.e., the rate of interest, falls into line with the common value of the marginal efficiency of other assets as determined by other forces. My theory, on the other hand maintains that this is a special case and that...the opposite is true, namely that the marginal efficiency of money is determined by forces partly appropriate to itself, and that prices move until the marginal efficiency of other assets fall into line with the rate of interest.

[1973b, p. 103]

## V. Extensions of the General Theory

Thus there were two possible lines of development: extension of the short-period

Marshallian (or Hicks' Walrasian) aggregate supply and demand framework to analyze factors such as capital accumulation, which were traditionally treated as "long period" problems, or analysis of a monetary economy where money is a determinant of the investment decision within the own-rate framework. Most economists, including Keynes' younger colleagues, pursued elaboration of long-period analysis and Kahn, Robinson, Kaldor, Harrod, among others, built on the aggregate version of Marshall's short-period to tackle the long-period problems of capital accumulation and distribution. Thus the Harrod-Domar growth models spawned multiplier-accelerator models, and the analysis of capital accumulation produced the Cambridge theories of aggregate income distribution. It is characteristic of these latter theories that investment is exogenous, eliminating the need to discuss the monetary elements which Keynes had used in the *General Theory* to explain investment decisions. While investment and expectations play a crucial role in the post-Keynes Cambridge theories, the fact that they were considered exogenous made analysis of the monetary factors Keynes considered crucial to their determination unnecessary. Of little importance to the formulation of short-period aggregate supply and demand, monetary factors and Keynes' concerns for cyclical instability had even less importance in the extension of these constructions to stable long-period equilibria.

For economists who preferred Hicks' Walrasian version, the analysis of long-period problems such as capital accumulation suggested flexibility of wages and prices, and variation in the rate of interest adjusting capital intensity to produce full employment. It was thus the aggregate supply and demand version of Keynes' theory, incorporated into traditional theory as a temporary general equilibrium with fixed prices, that failed transition to long-period conditions of flexible prices and production coefficients; the Cambridge objections to these formulations, made in Marshallian terms, had little impact. Indeed, in the Cambridge capital theory debates it was necessary to abandon Marshall and resort to Sraffa's theory of prices to

demonstrate the unlikely conditions required for the traditional results, but this left Keynes' theory still characterized by *ad hoc* short-period rigidity.

Joan Robinson, after a long career forging the long-period extension of the Marshallian short-period version of Keynes, finally rejected this approach in favor of the study of "historical" time, but has recently suggested (1978) that post-Keynesian analysis should be extended to reconcile Keynes and Sraffa. This would imply integrating Keynes' essential monetary relationships with Sraffa's. Keynes' extension of Sraffa's commodity rate analysis to a monetary economy was clearly an attempt to respond to Hayek by showing just exactly why money was not neutral. Just as Sraffa went on to develop a similar framework to specify the essential logical relations between distributive variables and relative prices, Keynes' extension of the interest rate parity theorem can be considered as the identification of the logical relations between the money rate of interest and the level of output and employment in a monetary economy. While Sraffa's relations imply no particular causal relationships, Keynes' system explicitly proposes money as the real or causal variable constraining a capitalist or monetary production system. It is the recognition of this role of money that has been absent from Cambridge, and all other, macroeconomics after Keynes.

Recently, there has been a renewal of interest in Keynes' monetary analysis. For example, Paul Davidson (1972) analyzes investment in terms of spot and future prices, drawing on the monetary detail of the *Treatise* to support liquidity preference, while Hyman Minsky (1975) has linked the role of aggregate expenditure to the determination of the relative prices of consumption goods and capital assets to identify the influence of the financial system on investment cycles. Luigi Pasinetti's (1981) discussion of the relation between natural rates and the social relations producing money rates of interest builds on similar factors. I (1982, 1983) and E. J. Nell (1983) attempt to draw direct links between the concepts of own-rates in Keynes and Sraffa.

From Hicks's reformulation of Keynes' supply and demand analysis in Walrasian terms to Don Patinkin's recent emphasis on its Marshallian origin, the profession (with the exception of D. Dillard, 1954, and more recently A. Barrère, 1985) has considered the principle of effective demand independently of Keynes' explicitly announced intention to analyze a monetary production economy and his claim that the distinctive aspect of his theory was to be found in the essential properties of interest and money which made the latter a real factor and the former a monetary factor. Recognition of this distinction as expressed in Keynes' own-rate framework may yet produce the monetary revolution in economic theory promised by Cambridge economics after Keynes.

# Cambridge Price Theory: Special Model or General Theory of Value?

By BERTRAM SCHEFOLD\*

Keynes and Marshall liked to emphasize the continuity of their thought with the classical Ricardian tradition. Although this affinity concerned aspects of their theories which were, as theories of value, essentially neoclassical, the followers of Keynes—Joan Robinson in particular—began to return to a classical analysis of prices after the foundations of the neoclassical theory of output had been shaken by Keynes. The ground for this had been prepared by the debate about increasing returns (in which Sraffa's contribution was prominent), the recurrent discussions about capital theory and the study of classical authors. The appearance of Sraffa's *Production of Commodities by Means of Commodities* marked a second revolution of Cambridge economics in this century. Neoclassical economists have reacted to Sraffa's departure much in the same way as they had reacted to Keynes': by trying to integrate the new ideas as special cases of the old doctrine. However, the Cambridge price theory is, contrary to Frank Hahn (1982), not a model within the neoclassical universe, but a reformulation of the classical theory.

The general equilibrium of the long period is by definition an equilibrium in all markets, including the capital market, so that it must be characterized by a uniform rate of profit. If homogeneous commodities are produced by single-product industries, Sraffa's price equations are

$$(1) \quad (1 + r)Ap + wl = p,$$

where the coefficient  $a_{ij}$  of the input-output matrix  $A$  denotes the amount of commodity

$j$  and  $l_i$  the amount of labor required to produce one unit of output in industry  $i$ , where  $p$  is the price vector,  $w$  is the wage rate, and  $r$  the rate of profit.

The socially necessary technique and the level and composition of output are considered as given (constant returns are not assumed). The determination of the composition of output through individual preferences is formally not ruled out, but other explanations are available. The theory of distribution is treated as a separate issue. The function of prices is to provide a measure of normal costs against which the profitability of alternative technologies and future investments can be estimated.

Prices of production are such that the economic system can reproduce itself in its actual state of growth or decline if the underlying conditions remain unchanged. If they do change, the system will enter a new long-period position with new prices of production. The prices of production act as centers of gravitation for market prices, but this does not mean that market prices will necessarily ever get very close to prices of production; the theory only denies that the discrepancy between market prices and prices of production can become permanently large, involving considerable losses or surplus profits, while the fundamental conditions remain the same. The cause for the gravitation of market prices is the tendency for the equalization of rates of profit in different industries. But the process may take diverse forms. Apart from changes in prices themselves, transfers of funds, investment, capital losses and the fixation of surplus profits as rents through the establishment of new property rights are all important. New institutions which confirm the tendency are invented as often as institutions which upset it. The classics were therefore not very interested in the many conceivable models that might describe processes of gravitation.

\*FB 2, J. W. Goethe-Universität, Frankfurt/M., Germany. I thank V. Caspari, G. Duménil, G. Englmann, J. Eatwell, P. Garegnani, D. Lévy, and others for helpful discussions.

In modern times, adjustment of capacity utilization at unchanged prices seem often to be more important than changes of market prices for the adaptation of supply and demand to temporary disturbances. Prices and markups reflect the conditions that would prevail if production were steady at normal capacity utilization. Up to a point, changes in demand can then be met through adjustments in stocks, orders, and levels of operation without changes of prices so that market prices can actually be equal to prices of production although profitability fluctuates as with changing market prices.

At any rate, prices of production are conceptual magnitudes defined for the analysis of an economic system in a given state of accumulation. They are necessary as measures for the distribution of the surplus, for the quantity of capital, and for the analysis of different forms of technical progress.

The concept of equilibrium and of stability is different in *modern* neoclassical theory. If the economy is not in a stationary or atemporal equilibrium (with which we are not concerned here), one modern neoclassical method is that of *temporary* equilibrium. In such an economy, there is no trading in forward markets. Prices will be such that, in a given state of expectations, markets clear and existing stocks can be used to produce goods according to the anticipated state of future demand. Such a model deals only with market prices in the short run. Moreover, the stability of this kind of equilibrium is problematical, because small accidental deviations may alter the expectations which define it.

Alternatively, the atemporal equilibrium model is extended to an *intertemporal* one with a finite or infinite horizon; there are then present markets for future deliveries, in terms of discounted prices. Contracts can be contingent on changing future states of nature. It is therefore possible to represent the classical problem of growth with technical change, but not as a process going on through time. Instead, that set of prices is chosen which will coordinate demand and supply in present and future markets simultaneously, given the expected changes in the structure of production and consumption. Positive prices are exchange ratios which clear pre-

sent and future markets. At the same time, they define the factor income by households and differential profits (obtained by firms under advantageous conditions and distributed to households). But, to the extent that production takes time, inputs to a given process are not valued at the same prices as outputs. Each good exists at a particular point in time and is to be valued at the prices which bring contracts for deliveries for that moment of time into equilibrium.

The own-rate of interest of a commodity can be defined as the maximum excess (in percent) that can be obtained of a commodity at the end of a period over one unit of the commodity invested in the beginning. In an intertemporal equilibrium with discounted prices, this must be equal to the ratio of the price at the beginning divided by the price at the end.

It is well known that there may be as many own-rates of interest as there are commodities in a neoclassical intertemporal equilibrium. The own-rate of interest is equal to something that looks like the unique rate of profit in the classical system if a commodity or commodity basket is taken as the numeraire: let  $a_i$  be a vector of inputs (including factors) in period  $t$  to a process  $i$  which yields outputs  $b_i$  at the beginning of period  $t+1$  in an intertemporal equilibrium with price vectors  $p_t$  and  $p_{t+1}$  for the beginning and the end of period  $t$ . No net profits will be made in a neoclassical intertemporal equilibrium at *discounted* prices so that  $a_i p_t = b_i p_{t+1}$  for all processes  $i$ . However, we can express prices in each period in baskets of goods given by some vector  $d$ —this includes the case where  $d$  represents a producible monetary commodity. These *undiscounted* prices in terms of numeraire  $d$  may be denoted by  $p_d$ ; we have  $p_{d,t} = p_t / dp_t$  so that we may calculate a rate of return  $r_d$  for process  $i$  in terms of commodity basket  $d$  and obtain

$$(2) \quad 1 + r_d = b_i p_{d,t+1} / a_i p_{d,t} \\ = (b_i p_{t+1} / dp_{t+1}) / (a_i p_t / dp_t) = dp_t / dp_{t+1}.$$

If we reckon in terms of undiscounted prices, all processes are therefore equally profitable but the rate of return depends on the commodity chosen as the numeraire; it is equal

to the own-rate of interest of the standard of prices in each period.

All own-rates of interest are necessarily equal only if the vectors of relative prices are proportional in different periods as in the classical model. As a matter of fact, Sraffa was the first to provide a skeptical account of the multiplicity of own-rates of interest in intertemporal equilibrium in his review of Hayek (1932). Hayek had been looking for a "natural" rate of interest which might guide monetary policy; it turned out that his intertemporal equilibrium contained many. Ever since, neoclassical theorists have been pursuing the impossible task of finding "the" rate of interest in intertemporal equilibrium as a monetary phenomenon while preserving the neutrality of money. One approach is based on the empirical lack of forward markets and leads back to a temporary equilibrium in which there are forward markets for only one monetary commodity which yields the rate of interest. This again raises the question mentioned above of what stability such an equilibrium might have if expectations are not derived from fundamental data such as innate preferences. Moreover, it is not clear how this would have to be extended to an analysis of accumulation going on through time in a sequential process. In particular, the point of view of intertemporal equilibrium suggests that the rate of interest depends on long-term contracts while the post-Keynesians in Cambridge have emphasized the possibility of a dependence of the rate of interest on short-run phenomena that may be independent of the more permanent influences on the rate of profit in industry.

The strangest aspect of the modern intertemporal equilibrium theory concerns the treatment of initial endowments; they are treated as given so that in general some will be in excess supply and will receive zero prices if there are limited possibilities of substitution. The rates of return are therefore not uniform in that the stocks in excess supply yield no return at all. Hence, the fundamental condition of a long-period equilibrium is violated. Moreover, according to a distinct second argument, the stocks must once have been acquired in order to use them

profitably so that, if they now turn out to be superfluous, we are faced with a short-period problem of adaptation and the deceived expectations should—but do not in the model—influence the future course of events. This is not a mathematical but a conceptual inconsistency. The model is often defended on the grounds that the entire future allocation over the given time horizon is settled afresh by means of forward trading. Against this, one may not only doubt the empirical validity of the assumptions but may also ask why this foresight did not exist yesterday to prevent the wrong stocks from accumulating. The intertemporal model like the temporary one, does not therefore, represent a "true" equilibrium for all markets, since it fails to take into account the heritage of stocks from the past with their associated expectations, in an analysis of what should be called a disequilibrium situation. The intertemporal model is not wrong because it fails to formalize expectations explicitly, for what matters is what generates expectations. It is a hybrid mixture of long-period equilibrium with uniform rates of return (but they are in general not uniform for endowments) and short-period adaptations to normal conditions (but then the disturbances should be treated as such even if expectations are only implicit). Finally, no distinction is made between the reaction of investment to temporary surpluses or shortages in particular industries on the one hand, and changes of aggregate effective demand on the other.

Unfortunately, classical and neoclassical models tend increasingly not to be compared as fully developed economic theories of value, money, employment, growth, and development; the tendency is to confront directly only the theories of value. If these are not (as, for example, by Schumpeter) seen in their contexts, the comparison may be reduced to a confrontation of the formal properties of models. It may then appear that the classical theory as represented by Sraffa's equations is only a special case of the intertemporal general equilibrium. The argument is that the classical model is characterized by a uniform rate of profit, with undiscounted prices of outputs and inputs being the same. Price vectors in the neoclassical model are

proportional if there is balanced growth. Hence it is concluded that the classical model can only be concerned with the situation in which endowments and preferences happen to be such that the economy can start and follow a process of balanced growth.

As a matter of fact, there are important contextual differences between classical and neoclassical theories even if balanced growth is assumed or attained. Joan Robinson was concerned with the analysis of "Golden Ages" where she supposed stocks already to have been inherited in a balanced composition because those stocks had been accumulated with a view to sustain future growth. She then examined the conditions, in particular in relation to effective demand, which would sustain expectations consistent with growth at various levels of employment.

Now it should be clear that *balanced* growth plays a special role in *neoclassical* theory because, with constant returns and constant preferences, the economy will be close to a balanced growth path (turnpike theorem) anyway and, more importantly, because different scarcities of different capital goods will not be present and cause unequal rates of return in terms of the same standard in the "steady state." But the problem of *unbalanced* growth or of structural change had been one of the main concerns of *classical* theory from its early beginnings.

Ricardo's vision of the extension of cultivation to inferior lands with the growth of population in the process of accumulation involved such a structural shift, and he analyzed it by comparing what we now call systems of prices of production in subsequent long-period positions, where the rate of profit could be uniform in each, because the growth of receipts over costs on better lands was absorbed by rents. Changes in the composition of output due to the influence of varying income elasticities with the growth of real incomes can be dealt with by means of the same method. Finally, technical progress causes profit differentials which express the fact that two systems, corresponding to an "old" and a "new" technique, coexist for some time. The differential will be the more lasting the greater is the market power of firms, but imperfections of competition have

to be treated as a separate matter, and the comparison of long-period positions remains the essential step of the analysis.

There are special cases of structural change which are analyzed best by admitting a slow, continuous shift of the input-output coefficients. The outstanding examples are the effects of technical progress as they appear at higher levels of aggregation in Leontief systems, or the change in the composition of output that accompanies rises of real incomes and is described by Engel curves. If the coefficients of  $A$  and  $l$  depend on time and follow some foreseeable pattern, prices will do the same. The unique rate of profit can still be defined if the movement is slow relatively to the movement of production; one then has, in obvious notation

$$(3) \quad (1 + r_t)A(t)p_t + w_t l(t) = p_t.$$

The own-rate of interest as defined above is for each commodity  $i$  equal to the rate of profit. But it is in general not equal to  $p_{t,i}/p_{t+1,i}$ , because we are here dealing with undiscounted prices.

Key problems of the theory of unbalanced growth arise if the process of change is accelerated so that, for instance, the consumption of some commodities shrinks faster than capacity for their production does because of wear and tear. Such an increase of excess capacities may have implications for aggregate effective demand and destroy the stability of the long-period position. The discontinuity must then again be analyzed in terms of comparisons of equilibria.

If structural change is fast, one might like to introduce shifts of relative prices by allowing relative prices at the beginning of the period to be different from those at the end. But is easy to see that effects of changes in distribution are then not easily distinguished from effects of changes in the standard of prices. To make a strong case, suppose we had  $A(t), l(t)$  depend on time  $t$ , with  $t = \dots -1, 0, 1, \dots$  stretching indefinitely back into the past and into the future. It is assumed that markets clear at positive prices (no excess stocks) in each period and that relative prices fulfill the infinite series of

equations, which defines a Golden Age with structural change:

$$(4) \dots, (1 + r_t)A(t)p_t + w_t l(t) = p_{t+1}, \dots$$

Under suitable assumptions prices are determined uniquely. If, for instance, productivity grows at rate  $g$  so that  $l(t) = l_0(1 + g)^{-t}$ , if  $A(t) = A$  and  $r_t = r$  are constant, and if the rise of the wage rate compensates productivity gains  $w_t = w_0(1 + g)^t$ , one obtains constant prices and  $r$  is the rate of profit as in a Sraffa system. If  $w_t = w_0$  is constant, prices fall with the rate of productivity  $g$ , but each own-rate of interest exceeds both  $r$  and  $g$  and the deflation implies that the rate of profit exceeds  $r$ . Conversely, wage rates rising faster than productivity lead to an inflation which will let profits appear higher than they really are (if the wage rate rises at rate  $h$ ,  $p_{t+1} = ((1 + h)/(1 + g))p_t$  and the rate of profit is  $(1 + g)(1 + r)/(1 + h)$  at constant prices).

This lack of transparency indicates that the traditional method of analyzing structural change by means of comparisons of equilibria is preferable. The method of production in (3), reached after each gain in productivity, is considered as socially necessary; market prices will adjust to the prices of production so defined with a time lag. But if one insists on using an "intertemporal" system as in (4), with relative prices changing, for example, because of different rates of growth of the productivity of labor in different sectors, the equilibrium is not determined and little can be said about distribution (i.e., the real wage and the rate of profit), before the movement of the wage rate has been specified and the system is reformulated in terms of equations (3).

In spite of the familiar analogy with the compensation of the differences in the rates of interest between two currencies through differences in the spot and forward exchange rates, it is not clear whether an analysis of production in terms of an intertemporal price system could be of much relevance even apart from the lack of transparency. For it involves on the one hand, like an analysis of market prices, quick changes in relative natural prices while, on the other, rates of return are uni-

form, yet changing, multiple and none is easily linked with money in the absence of a *produced* money commodity. As Garegnani has pointed out to me, it would not be *logically* impossible to extend the classical analysis in this direction but gains for the theory of accumulation are not obvious. Sraffa did not use "dated" prices in *Production of Commodities* in spite of several allusions to structural change (inventions, expansion of production to inferior lands etc.), and he attributed the origin of different own-rates of interest to changing "market prices" in his review of Hayek.

It is well known that a logical critique of the neoclassical theory of distribution using aggregate measures of capital has been attempted on the basis of the classical theory. I do not want to discuss here how other new versions of the neoclassical theory of distribution are affected by it. But the generality of the classical theory is enhanced by the fact that it is compatible with several theories of distribution which may each be more or less pertinent in different historical circumstances. To start from a given real wage and to regard profits as a residual was a first approach taken at a time when real wages had shown a remarkable stability over centuries in spite of short-term fluctuations. Others have argued that imperfect competition determines a degree of monopoly so that we should first explain the share of profits in national income which then determines the rate of profit. The Cambridge school has stressed the role of demand that, given different savings propensities of capitalists and workers, effects a redistribution of incomes between classes such that—within limits—a higher ratio of investment to output can be financed because savings rise with a rising share of profits. In this view, accumulation is so dynamic that prices can be kept above costs for considerable stretches of time in spite of the forces of competition. Firms are thus able to finance their expansion out of profits, that are high because the demand—largely generated by the firms themselves—is booming. Sraffa has suggested that the rate of profit is determined from outside the system of physical reproduction by the level of the monetary rates of interest. A very simple

version of this theory would hold in a situation of slow accumulation where competitive firms are indebted to the banking sector so that their profits must cover interest costs while competition keeps prices down and real wages absorb what is left of the net product.

The price theory under discussion can therefore not be subsumed as a special model under the neoclassical theory. It is general in that it is compatible with a number of alternative theories of distribution and output which have not yet all been formalized with the same degree of rigor and depend in their applicability on historical circum-

stances, but which, taken together, are related as variants of the classical theory and cover a wide range of empirical phenomena.

# Joan Robinson's Critique of Equilibrium: An Appraisal

By E. ROY WEINTRAUB\*

Joan Robinson devoted much of her energy to critiquing equilibrium analysis, or what she was accustomed to calling Walrasian economics. In her various writings she returned again and again to the idea that Walrasian economics necessarily misdirected analysis in macroeconomics, capital theory, distribution theory, and value theory. Many of her writings made mention of Walrasian equilibrium, usually in the context of the wrong way to look at a particular problem. Indeed, for Robinson, the Walrasian theory came to stand for the intellectual opposition, as it were, for the "others" who had got it wrong, where the "it" was anything from the measurement of capital to the role of expectations in long run investment decisions.

My task today is a simple one. First I shall identify the central elements of Robinson's attack on Walrasian economics and then sketch what modern authors now understand to be the main points of the "neo-Walrasian research program." Finally, I shall compare Robinson's understanding of, and critique of, that program with the program itself. From this, I shall argue that Robinson's analysis flowed from her flawed understanding of the nature and role of equilibrium in the neo-Walrasian program.

## I. Robinson on Equilibrium

In their excellent survey article, Harvey Gram and Vivian Walsh note that "the theorist who would fairly appraise Robinson's work must immediately come to terms with the correct interpretation of her many attacks upon general equilibrium theory and comparative static analysis. She means by general equilibrium theory the static and intertemporal models of supply and demand equilibrium in the post-Walrasian tradition..." (1983, p. 519).

In "History and Equilibrium," Robinson noted that Frank Hahn had identified the competitive equilibrium as a set of prices such that, were they to obtain, no agent would have any incentive to modify any decision. She then stated:

This entails that everyone knows exactly and in full detail what consequences would follow any action that he may take.... Equilibrium is described as the "end of an economic process"; the story is usually told of a group of individuals each with an "endowment" of ready-made goods or productive capacity of some specific kind. By trading and re trading in a market, each ends up with a selection of goods that he prefers to those that he started with. If we interpret this as an historical process, it implies that, in the period of past time leading to "today," equilibrium was not established.... A system of simultaneous equations need not specify any date nor does its solution involve history. But if any proposition drawn from it is applied to an economy inhabited by human beings, it immediately becomes self-contradictory. Human life does not exist outside history.... [1979, p. 49]

Robinson lodged two separate objections to the idea of a competitive equilibrium. First, she faulted the neo-Walrasian model for ignoring real life concerns that give legitimacy to the activity of doing economic analysis. And second, she blamed the neo-Walrasian idea of equilibrium for necessarily biasing the conclusions of economic arguments in favor of a particular political-moral order.

As an example of the first kind of attack, consider her "The Disintegration of Economics." She argued:

The theory of market equilibrium, with given "endowments" and given "tastes" for a specific list of commodities is

\*Professor of Economics, Duke University, Durham, NC, 27706

essentially static. It can accommodate accumulation and change only by making the assumption that buyers and sellers have "correct foresight" of the future course of prices. A world of correct foresight is not the world in which human beings live. [1979, p. 94]

To illustrate the second type of attack on equilibrium notions, consider the following passage, from the same paper:

The great claim of equilibrium theory was that it showed how scarce means are allocated between alternative uses in accordance with consumers' tastes. The existence of scarce means (materials, energy, cultivable land) has recently come to the fore in public discussion, while consumers' tastes run to large cars, overheated rooms, and an excessive consumption of meat. The central doctrine of orthodox economics is the defence of the freedom of anyone who has money to spend, to spend it as he likes. [p. 92]

These illustrations of Robinson's criticisms of the neo-Walrasian idea of equilibrium merely sample the "identification she makes between neo-neoclassical economics—the object of many of her attacks—and post-Walrasian general equilibrium theory..." (Gram and Walsh, p. 519). It is not necessary here to examine other cases of Robinson's annoyance with the idea of equilibrium as it is used in neo-Walrasian analysis. It is necessary, however, to be quite clear about the object of her derision, for if her understanding of neo-Walrasian analysis is faulty, her attacks on it may be without merit.

## II. The Neo-Walrasian Research Program

As I have shown elsewhere (1985) it is helpful to think of general equilibrium analysis as a scientific research program in the sense in which the term was first used by the philosopher, Imre Lakatos. (See Mark Blaug, 1980.)

A research program in the sense of Lakatos is a constellation of theories linked by certain elements. That is, all the theories are

based on a certain set of presuppositions shared by all who work in the program. The organizing center of the program is called the hard core, which contains propositions taken as given by adherents to the program. The heuristics of the program suggest the ways that theories can be developed from the hard core. The heuristics are used to develop theories in the protective belts of the program. The core is never subjected to testing; rather it is the induced theories that are the appropriate subjects for corroboration and falsification.

As with any Lakatosian research program, the neo-Walrasian program is characterized by its hard core, heuristics, and protective belts. Without asserting that the following characterization is definitive, I have argued that the program is organized around the following propositions: HC1 *economic agents have preferences over outcomes*; HC2 *agents individually optimize subject to constraints*; HC3 *agent choice is manifest in interrelated markets*; HC4 *agents have full relevant knowledge*; HC5 *observable outcomes are co-ordinated, and must be discussed with reference to equilibrium states*.

By definition, the hard-core propositions are taken to be true and irrefutable by those who adhere to the program. "Taken to be true" means that the hard-core functions like axioms for a geometry, maintained for the duration of study of that geometry.

The positive and negative heuristics of the program link the hard core with the basic work of theory construction and development. The standard process of empirical conjectures and refutations is associated with the protective belts of the program. The heuristics of the neo-Walrasian program consist of propositions like: PH1 *construct theories in which economic agents optimize*; PH2 *construct theories that make predictions about changes in equilibrium states*; NH1 *do not create theories based on irrational behavior*; NH2 *do not create theories in which equilibrium has no meaning*; NH3 *do not test hard-core propositions*; and so forth.

The heuristics link the hard core to the theories in the belts that are the fit subject for testing and refinement. I submit that theories like human capital theory, "rational

expectations macroeconomics," the theory of black-white earnings differentials, and the theory of optimum tariffs, are theories in the protective belts of the neo-Walrasian research program. These theories are all based on the hard core, and the refinements and developments of these theories are guided by the heuristics of the program. Notice that we do not test the hard core propositions, as we do not test (with the idea of confirmation or rejection) the inverse square law in Newtonian mechanics, or the fixity of the earth's position with respect to the sun in the Ptolemaic program in astronomy—these are hard-core propositions that are maintained by workers in the program. The issue of whether, and when, a program (defined by the hard core) is "rejected" is an issue of the relative progress or degeneration of the program *with respect to a competing research program*. There is no evidence to suggest that economists abandon degenerating programs in the absence of a progressive alternative. We do not, in the face of falsified theories in the belt of a program, abandon that program until there is an alternative program with theories that are themselves corroborated.

The perspective of the neo-Walrasian program allows us to see that the notion of a "Walrasian" equilibrium is indeed fundamental to the enterprise that Robinson called "neo-neoclassical" economics (which roughly corresponds to my term "the neo-Walrasian program"). Using the same hard core and heuristics, neo-Walrasian economists create models of investment behavior, study the effect of open market operations on the level of real output and employment, and explain wage differentials between rural and urban workers in developing economies. All these economists, in their studies, use models which *interpret* the terms "agent," "optimize," "constraint," "knowledge," "market," and "equilibrium" in ways appropriate to the particular model. A coherent analysis will require a demonstration that an equilibrium exists for the model thus constructed. Predictions, and empirical corroborations or falsifications of those predictions, will be induced by the equilibrium concept that is consistent with the specification of the model.

### III. Robinson's Critique: An Appraisal

Returning to Robinson's critique of the neo-Walrasian idea of equilibrium, it is absolutely clear that her first set of objections to the notion of equilibrium is based on a profound misunderstanding of the concept of equilibrium and its function in analysis. The preceding section has shown that coordinated outcomes, equilibria, are imperfectly interpreted terms of the hard core of the neo-Walrasian program. Thus it is an organizing feature of any theory in the program that there must be a well-defined idea of equilibrium present; that equilibrium notion is to be intrinsic to any model or theory that exists in the protective belts.

It is a categorical mistake to complain that the Arrow-Debreu-McKenzie (model specific) competitive equilibrium is unrealistic or that it assumes knowledge of the consequences that would follow any action that an agent would take. Such corroborative tests are appropriate for theoretical constructs associated with the protective belts, but are not appropriately directed to the terms and structures of the hard core. All that Robinson's criticisms demonstrate is that she is not used to engaging in neo-Walrasians analysis, something that people perhaps knew already. To repeat, her criticisms of the idea of equilibrium itself, which focus on its presumed lack of realism, only identify Robinson as one who works in a different program.

Many of Robinson's attempts to convict neo-Walrasians of logical error are flawed in this way. The equilibrium notion is not testable, it is simply present as an organizing feature of the theories in the protective belts of the program. A monetary theoretic model's "perfect foresight equilibrium" can neither be corroborated nor falsified. Yet it is not meaningless to work with such equilibria if they lead to propositions that are potentially falsifiable.

From this perspective it becomes clear that Robinson adhered to an alternative program, perhaps one that would be termed the post-Keynesian program, and her criticisms of the neo-Walrasian program must be read as rhetorical set-pieces designed to gather new ad-

herents to her preferred program; that is, her arguments are for the most part exhortations, not exercises in theoretical or empirical logic.

Robinson also argued that the neo-Walrasian program biases the kinds of questions that economists can ask, and answer. In so arguing, for example, she identified economists who believe in the value of neo-Walrasian equilibrium notions with people whose "tastes run to large cars, overheated rooms and an excessive consumption of meat." This line of argument is suggestive of a moralist, not an analyst. Curiously, preaching *is* one of the few ways that one *can* attack a progressive research program like the neo-Walrasian program. Recent work by Arjo Klammer (1984) and Don McCloskey (1983) holds that such rhetoric is less disreputable in science than a rationalist's construction of the growth of knowledge would suggest.

Put another way, the choice which a scientist makes between two competing research programs will be based, using a rational reconstruction of the growth of knowledge, on the relative progressivity of the programs themselves. But such reasoned judgments are, in practice, not often found. The programs may compete for adherents with arguments that transcend reason. Moral suasion may be appropriate to coax a potential convert to the cause, the emergent program. Whether the convert finds the new religion congenial may later depend on the actual progressivity of the program as tested by the theoretical and empirical progress it demonstrates, but in the first instance, converts may be won by emotion, not reason.

#### IV. Conclusion

As a matter of logic, Joan Robinson's criticism of the nature and role of equilibrium in the neo-Walrasian program cannot withstand close scrutiny. Assailing the logic of hard-core propositions, as she did, is an exercise based on misunderstanding. As an attempt to gather adherents to a competing research program, Robinson's moralizing is explicable. The ultimate issue of course is the relative progressivity of the neo-Walrasian and post-Keynesian research programs. What is required to judge the issue is a comparative appraisal of those two competing research programs. It is a bit troubling that no such appraisal has as yet been attempted.

## OPEN AND SEALED-BID AUCTIONS†

### Auction Theory with Private Values

By ERIC S. MASKIN AND JOHN G. RILEY\*

For many centuries, auctions have been a common form of selling procedure. Although auction methods vary across country and product, the two most frequently observed are the open, ascending bid (or English) auction and the sealed-bid auction. Recent theoretical research has led to a theory of equilibrium bidding in these two auctions and a wide range of alternatives as well. As a result it has been possible to compare the revenue extracted by the seller under different auction methods and even to characterize the revenue-maximizing auction.

The Revenue Equivalence Theorem (see for example, William Vickrey, 1961, Roger Myerson, 1981, and Riley and William Samuelson, 1981) asserts that when each bidder's reservation price for a unit of an indivisible good is an independent draw from the same distribution, and bidders are risk neutral, the sealed-bid auction generates the same expected revenue as the open auction. Much recent research has involved weakening each of the main hypotheses—risk neutrality, identically distributed values, and independence of values—in turn. We shall illustrate some of the principal conclusions of this work by considering the properties of open and sealed-bid auctions in a model of two bidders whose reservation prices can assume only two values, and by comparing these auctions to the “optimal” or revenue-maximizing auction.

†*Discussant:* William F. Samuelson, School of Management, Boston University.

#### I. Revenue Equivalence

Imagine that the reservation price of bidder  $i$  ( $i=1,2$ ) can assume the values  $v_H$  (with probability  $p$ ) and  $v_L$  (with probability  $1-p$ ), where  $v_H > v_L \geq 0$ . Bidders' values are private information and independently distributed. Bidders are risk neutral, that is, they maximize the expression

$$(1) \quad (\text{probability of winning})v \\ - \text{expected payment.}$$

We suppose that an open auction proceeds by the auctioneer's continuously raising the asking price. The auction concludes when one of the bidders drops out. The remaining bidder is the winner and pays the dropout price (if both bidders drop out simultaneously, a coin is flipped to determine the winner). Given these rules, one can easily confirm that a bidder's unique (perfect) equilibrium strategy is to drop out when the asking price reaches his reservation price. (There are other “nonperfect” equilibria, see our 1983a paper). Thus the expected payoff of a  $v_L$  bidder (a bidder whose reservation price is  $v_L$ ) is zero, and his probability of winning is  $\frac{1}{2}(1-p)$ . The expected payoff of a  $v_H$  bidder, by contrast, is his surplus if the other bidder is “low” (since then the asking price only reaches  $v_L$  rather than  $v_H$ ) times the probability of that event, that is,  $(1-p)(v_H - v_L)$ . Since a  $v_H$  bidder wins when the other bidder has a low value and wins half the time when the other bidder has a high value, his probability of winning is  $\frac{1}{2}p + (1-p)$ .

In the sealed-bid auction, bidders submit bids simultaneously. The higher bidder is the winner (ties again are resolved by coin flips) and he pays his bid. Consider a symmetric

equilibrium. Because the distribution of values is discrete, the equilibrium will involve mixed strategies. Notice first that a  $v_L$  bidder (one whose reservation price is  $v_L$ ) will never bid more than  $v_L$  because, if he did, the maximum of such bids (if bidders use mixed strategies that randomize over a variety of alternative bids) would win the auction with positive probability, inducing a negative expected payoff. Let  $\underline{b}_L$  be the infimum of all bids submitted.

Suppose first that  $\underline{b}_L < v_L$ . Then bidders bid below  $v_L$  with positive probability and so a  $v_L$  bidder's expected payoff is positive. Suppose, furthermore, that bidder 1 bids  $\underline{b}_L$  with positive probability. Then bidder 2's chances of winning increase discontinuously if he bids just more than  $\underline{b}_L$  while his payment if he wins scarcely rises, thereby raising his expected payoff. But this is a violation of symmetry. On the other hand, if  $\underline{b}_L$  is not bid with positive probability, then bids near  $\underline{b}_L$  have almost no chance of winning, contradicting the positive expected payoff.<sup>1</sup>

Next let  $\underline{b}_H$  be the infimum of bids made by a  $v_H$  bidder. If  $\underline{b}_H > v_L$ , then a bid strictly between  $\underline{b}_H$  and  $v_L$  has the same chance of winning as  $\underline{b}_H$ , and so is preferable. Thus  $\underline{b}_H = v_L$ , and a  $v_H$  bidder's expected payoff must be  $(v_H - v_L)(1 - p)$ . In equilibrium, any bid  $b$  made as part of a mixed strategy must generate the same expected payoff. Therefore if  $F(b)$  is the cumulative distribution function of a  $v_H$  bidder's bid, it satisfies

$$(2) \quad [pF(b) + 1 - p](v_H - b) = (1 - p)(v_H - v_L).$$

By symmetry, a  $v_H$  bidder's expected probability of winning is  $\frac{1}{2}p + (1 - p)$ , whereas that of a  $v_L$  bidder is  $\frac{1}{2}(1 - p)$ . Because a given type of bidder's probability of winning and expected payoff are the same in the open and sealed-bid auctions, formula (1) implies that his expected payment is the same in the two auctions. We have established the Reve-

nue Equivalence Theorem for our model. Indeed, we obtain the same expected revenue from any other auction in which the high bidder wins, the expected payoff of a  $v_L$  bidder is zero, and the expected payoff of a  $v_H$  bidder is  $(1 - p)(v_H - v_L)$ .

It is of some interest to compare the open and sealed-bid auctions with a revenue-maximizing auction (see Myerson and Riley-Samuelson). Suppose that bidders were offered the choice between bidding  $v_L$  or  $b_H = (\frac{1}{2}v_H + \frac{1}{2}(1 - p)v_L)/(\frac{1}{2}p + 1 - p)$ , with, as always, the high bidder winning. Because  $b_H$  is greater than  $v_L$ , a  $v_L$  bidder will bid  $v_L$ . Since  $(\frac{1}{2}p + 1 - p)(v_H - b_H) = \frac{1}{2}(1 - p)(v_H - v_L)$ , a  $v_H$  bidder is indifferent between bidding  $b_H$  and  $v_L$ , and so might as well choose the former. Since a  $v_H$  bidder bidding  $b_H$  has the same probability of winning as in an open or sealed-bid auction ( $\frac{1}{2}p + (1 - p)$ ), but has a lower expected payoff,  $(\frac{1}{2}(1 - p)(v_H - v_L))$  rather than  $(1 - p)(v_H - v_L)$ , his expected payment must be higher. Thus, this alternative auction generates higher expected revenue. Indeed, it is optimal if  $v_L > pv_H$ . (If  $v_L < pv_H$  it is optimal to set a reserve price at  $v_H$ , thereby rejecting all lower bids.) In either case, the optimal auction differs from the open and sealed-bid auctions by prohibiting bidders from making certain bids. This conclusion generalizes to more complicated models, including those with a continuum of possible reservation prices.

## II. Risk Aversion

Let us modify the model of Section I only by supposing that bidders are risk averse. Let  $u$  be a strictly concave von Neumann-Morgenstern utility function, normalized so that  $u(0) = 0$ . A  $v$  bidder's payoff if he wins and pays  $t$  is  $u(v - t)$ ; his payoff if he loses and pays  $t$  is  $u(-t)$ .

Risk aversion does not alter the bidders' behavior in the open auction; it is still optimal for a bidder to drop out exactly when his reservation price is reached. Hence expected revenue is as before. In the sealed-bid auction,  $v_L$  bidders continue to bid  $v_L$ , and if  $F_R$  is the cumulative distribution function

<sup>1</sup>Our argument here presumes that the equilibrium in the sealed-bid auction is symmetric. One can show (see our 1983a paper) that there is no asymmetric equilibrium.

of a  $v_H$  bidder's bid, it satisfies the analogue of condition (2):

$$(3) \quad u(v_H - b)[(1 - p) + pF_R(b)] \\ = u(v_H - v_L)(1 - p).$$

The strict concavity of  $u$  implies that  $u(v_H - v_L)/u(v_H - b) < (v_H - v_L)/(v_H - b)$  for  $v_L < b < v_H$ . Hence, (2) and (3) imply that  $F_R(b) \leq F(b)$  with strict inequality for bids greater than  $v_L$  but less than the maximum. That is,  $F_R$  stochastically dominates  $F$ , and so the expected bid by a  $v_H$  bidder is higher with risk aversion than without. We conclude that, with risk aversion, a sealed-bid auction generates greater expected revenue than an open auction (see Gerard Butters, 1975, and Charles Holt, 1980). Intuitively, increasing a bidder's risk aversion heightens his fear of losing and so, in a sealed-bid auction, induces him to bid higher. Viewed alternatively, a sealed-bid auction, unlike an open auction, insures a winning bidder against fluctuations in the amount he has to pay, and a risk-averse bidder is willing to pay a premium—in the form of a higher bid—for this insurance.

By requiring payments even of losing bidders, an optimal auction (see our 1984 article, and Steven Matthews, 1983) can exploit the fact that a risk-averse bidder's marginal utility of income depends on whether he wins or loses. Let  $\pi_i$  be the probability of winning and  $b_i$  and  $a_i$  the payments by a winning and losing bidder, respectively, of type  $i$  ( $i = L, H$ ). An optimal auction chooses  $\pi_i$ ,  $b_i$ , and  $a_i$  to maximize

$$(4) \quad p(\pi_H b_H + (1 - \pi_H) a_H) \\ + (1 - p)(\pi_L b_L + (1 - \pi_L) a_L),$$

subject to

$$(5) \quad \pi_H u(v_H - b_H) + (1 - \pi_H) u(-a_H) \\ \geq \pi_L u(v_H - b_L) + (1 - \pi_L) u(-a_L)$$

$$(6) \quad \pi_L u(v_L - b_L) + (1 - \pi_L) u(-a_L) \geq 0$$

$$(7) \quad \frac{1}{2}p + (1 - p) \leq \pi_H$$

$$(8) \quad \frac{1}{2} \geq p\pi_H + (1 - p)\pi_L$$

$$(9) \quad \pi_H \geq 0 \quad \text{and} \quad \pi_L \geq 0.$$

Constraint (5), a self-selection constraint, ensures that a  $v_H$  bidder is at least as well off making a high as a low bid. We have omitted the analogous self-selection constraint for a  $v_L$  bidder since, as we shall see, it is satisfied automatically. Constraint (6) guarantees a  $v_L$  bidder a nonnegative expected payoff from participating. (Given (5), a  $v_H$  bidder's payoff will also be nonnegative.) Condition (7) says that a  $v_H$  bidder can win with at most probability 1 if the other bidder has a low reservation price and, given the symmetry of the model, with at most probability  $\frac{1}{2}$  if the other bidder's reservation price is high. Constraint (8) requires simply that each bidder's probability of winning, *unconditional* on his reservation price, not exceed  $\frac{1}{2}$ .

Letting  $\alpha$  and  $\beta$  be the Lagrange multipliers for (5) and (6), respectively, we obtain the first-order conditions

$$(10) \quad p\pi_H - \alpha\pi_H u'(v_H - b_H) = 0$$

$$p(1 - \pi_H) - \alpha(1 - \pi_H) u'(-a_H) = 0$$

$$(11) \quad (1 - p)\pi_L + \alpha\pi_L u'(v_H - b_L)$$

$$- \beta\pi_L u'(v_L - b_L) = 0$$

$$(1 - p)(1 - \pi_L) + \alpha(1 - \pi_L) u'(-a_L)$$

$$- \beta(1 - \pi_L) u'(-a_L) = 0.$$

From (10) we find that  $v_H - b_H = -a_H$ , that is, a high bidder is perfectly insured; he receives a monetary transfer  $-a_H$  ( $> 0$ ), as compensation if he loses. From (11) and the fact that  $u'(v_H - b_L) < u'(v_L - b_L)$ ,

$$(12) \quad (\beta - \alpha) u'(-a_L)$$

$$= 1 - p > (\beta - \alpha) u'(v_L - b_L).$$

Thus a  $v_L$  bidder is better off winning than losing ( $v_L - b_L > -a_L$ ). Moreover, since (from (12)) (6) is binding, he must actually pay a penalty if he loses ( $a_L > 0$ ), which we

can interpret  $a$  as an entry fee. Because (5) is binding and  $v_H - b_L > -a_L$ , we have  $v_H - b_H < v_H - b_L$ , that is, a  $v_H$  winner pays more than a  $v_L$  winner. If (8) is binding, as it will be if  $p$  is small enough, we can solve for  $\pi_L$  and rewrite (4) as  $p\pi_H(b_H - a_H - b_L + a_L) + pa_H + (\frac{1}{2} - p)a_L$ . From the above argument,  $b_H - a_H - b_L + a_L > v_H - v_L > 0$ . Hence, constraint (7) is binding:  $\pi_H = \frac{1}{2}p + (1 - p)$ .

We conclude that an optimal auction with risk-averse bidders resembles that for risk-neutral bidders. Bidders are offered the choice between two prices  $b_H$  and  $b_L$  (if, as before,  $p$  is not too high), and the high bid wins. However, if a bidder loses with a bid of  $b_H$ , he is compensated for losing, whereas if he loses with a bid of  $b_L$ , he is penalized. Intuitively, introducing a penalty heightens a risk-averse bidder's fear of losing and therefore increases the revenue that can be extracted from a  $v_H$  bidder. Of course, this penalty, by increasing risk, reduces the payment that a  $v_L$  bidder makes. But the penalty has no effect to the first-order, since, with no penalty, a  $v_L$  bidder is perfectly insured.

It remains only to show that the solution to the program of maximizing (4) subject to (5)–(9) satisfies

$$(13) \quad \pi_L u(v_L - b_L) + (1 - \pi_L)u(-a_L) \\ \geq \pi_H u(v_L - b_H) + (1 - \pi_H)u(-a_H),$$

the self-selection constraint for  $v_L$  bidders. But (13) follows immediately from the fact that (5) holds with equality and  $\pi_H u'(v - b_H) > \pi_L u'(v - b_L)$  (since  $\pi_H > \pi_L$  and  $b_H > b_L$ ) for all  $v$ .

### III. Asymmetry

Let us revert to risk neutrality but now drop the assumption that valuations are identically distributed. Specifically, assume that bidder 1's reservation price is distributed as in Section I, but that bidder 2's reservation price is either  $w_H$  or  $w_L$  with probabilities  $q$  and  $1 - q$ , respectively. Continue to suppose that the two bidders' distributions are independent. For convenience, let us suppose that  $v_L = w_L = 0$ . Then the

expected revenue generated by the open auction is

$$(14) \quad pq \min\{v_H, w_H\}.$$

We wish to compare the difference in revenues,  $\Delta$ , between the sealed-bid and open auctions.<sup>2</sup> To do this we shall consider two polar cases of asymmetry: (i) both bidders have the same probability of being high but have different high values, that is,  $p = q$  and  $v_H \neq w_H$ , and (ii) both bidders have the same high values but different probabilities, that is,  $v_H = w_H$  and  $p \neq q$ .

It is not difficult to see that in case (i),  $\Delta$  is positive. We know from Section I that when  $v_H = w_H$ ,  $\Delta$  is zero. Now imagine raising  $w_H$  above  $v_H$ . This does not affect revenue from the open auction since there is no change in the distribution of the second highest reservation value. However, with a higher  $w_H$ , the optimal response in the sealed-bid auction by bidder 2 (when  $v = w_H$ ) to bidder 1's equilibrium strategy is a higher bid. Bidder 2's higher bid, in turn, induces bidder 1 to bid higher than before (for details, see our 1983b paper). Hence, revenue from the sealed-bid auction rises, and  $\Delta$  becomes positive.

In case (ii), expected revenue in the open auction is  $pqv_H$ . In the sealed-bid auction, the equilibrium cumulative distribution functions,  $F_1$  and  $F_2$ , of the bids of bidders 1 and 2, when their reservation prices are  $v_H$ , satisfy the analogue of (2):

$$(15) \quad (1 - q + qF_2(b))(v_H - b) \\ = (1 - q + qF_2(0))v_H;$$

$$(16) \quad (1 - p + pF_1(b))(v_H - b) \\ = (1 - p + pF_1(0))v_H.$$

<sup>2</sup>As our model is formulated, an equilibrium in the sealed-bid auction may not exist. The nonexistence problem, however, is an artifact of our allowing literally a continuum of possible bids. In fact, we can restore existence even with a continuum by allowing the possibility of positive but infinitesimal bids, which we implicitly assume in our analysis.

Notice that right-hand sides of (15) and (16) allow for the possibility that a  $v_H$  bidder will bid zero (actually, infinitesimally more than zero) with positive probability. This will be the case if  $p \neq q$  since both bidders must make the same maximum bid,<sup>3</sup>  $\bar{b}_H$ , when their reservation price equals  $v_H$ , and (15) and (16) can be satisfied for  $b = \bar{b}_H$  only if one of  $F_1(0)$  and  $F_2(0)$  is nonzero. For example, if  $p > q$ , then (15) and (16) imply that

$$\bar{b}_H = qv_H = pv_H(1 - F_1(0)),$$

and so  $F_1(0) = 1 - q/p$ . Integrating (15), we obtain  $qv_H$  as the expected payment by bidder 1 if his reservation price is  $v_H$ , where  $z = \int F_2(b) dF_1(b)$ . Similarly, from (16), the expected payment by bidder 2 is  $(p(1 - z) + q - p)v_H$ . Hence total expected revenue is  $q^2v_H$ , which is less than the open auction revenue,  $pqv_H$ . Therefore, for case (ii),  $\Delta$  is negative.

Roughly speaking, the sealed-bid auction generates more revenue than the open auction when bidders have distributions with the same shape (but different supports), whereas the open auction dominates when, across bidders, distributions have different shapes but approximately the same support.

#### IV. Correlation

Let us return to the model of Section I, except now assume that reservation prices are correlated across bidders. Specifically, let  $r_{ij}$  ( $i, j \in \{L, H\}$ ) be the joint probability that bidder 1's value is  $v_i$  and that bidder 2's value is  $v_j$ . Correlation implies that

$$(17) \quad r_{HH}r_{LL} - r_{HL}r_{LH} \neq 0.$$

As usual, behavior in the open auction remains the same, and so expected revenue is

$$(18) \quad r_{HH}v_H + (1 - r_{HH})v_L.$$

Making the obvious modifications in the

analysis of Section I, we conclude that expected revenue for the sealed-bid auction is also (18). This equivalence between the two auctions does not generalize to distributions with more than two point supports because, in general, with correlation, a higher reservation price does not imply a higher bid for the sealed-bid auction (although it does for the open auction).<sup>4</sup> Any condition sufficient to guarantee that bids are monotonic in reservation prices, however, ensures equivalence. One such condition is that the reservation prices be affiliated (see Paul Milgrom and Robert Weber, 1982).

When (17) holds, an optimal auction extracts all surplus from bidders (see Jacques Cr  mer and Richard McLean, 1985). To see this, let  $c_{ij}$  ( $i, j \in \{L, H\}$ ) be the payment that bidder 1 makes when his  $v = v_i$  and bidder 2's  $v = v_j$ . To extract all surplus, the  $c_{ij}$ s must satisfy

$$(19) \quad \frac{1}{2}r_{LL}v_L - r_{LH}c_{LH} - r_{HH}c_{HH} = 0$$

$$(20) \quad (\frac{1}{2}r_{LH} + r_{LL})v_L - r_{LH}c_{HH} - r_{LL}c_{HL} < 0$$

$$(21) \quad (\frac{1}{2}r_{HH} + r_{HL})v_H - r_{HH}c_{HH} - r_{HL}c_{HL} = 0$$

$$(22) \quad \frac{1}{2}r_{HL}v_L - r_{HH}c_{LH} - r_{HL}c_{LL} < 0.$$

Equations (19) and (21) require the surplus of  $v_L$  and  $v_H$  bidders, respectively, to be zero. Inequality (20) ensures that a  $v_L$  bidder is not better off bidding as a  $v_H$  bidder, and (22) imposes the corresponding constraint on a  $v_H$  bidder. But from (17), we can solve for  $c_{ij}$ s that satisfy (19)–(22).

<sup>4</sup>Suppose, for example, that  $v$  can take on three possible values:  $v_H > v_M > v_L$ . Assume that if  $v = v_H$  for one bidder, then it is very likely that  $v = v_L$  for the other bidder. Assume further that if  $v = v_M$  for one bidder, then the other bidder in all likelihood has the same reservation price. In this case, a  $v_M$  bidder will bid higher on average than a  $v_L$  bidder in the sealed-bid auction. Furthermore, the sealed-bid auction, at least for some parameter values, generates strictly more revenue than does the open auction.

<sup>3</sup>If, say, bidder 1's maximum bid were greater than that of bidder 2, bidder 1 could lower his bid without reducing his probability of winning.

### V. Concluding Remarks

We have discussed three major hypotheses of the Revenue Equivalence Theorem, but there remain two more implicit in our formulation. One is the assumption that only a single item is sold. If buyers have downward-sloping demand curves and there are multiple units for sale, the Revenue Equivalence Theorem again fails. Extrapolating from some simple examples, we conjecture that open bidding will tend to dominate sealed bidding in this environment.

The second assumption is that a bidder's reservation price does not affect the reservation price of any other bidder. This is the "private values" hypothesis: the assumption that reservation prices are a matter of taste rather than a reflection of information about the intrinsic value of the good. In the latter case, the "common values" model, the open auction tends to produce higher revenue than the sealed-bid auction when our other hypotheses are maintained (see Milgrom and Weber).

# Empirical Testing of Auction Theory

By ROBERT G. HANSEN\*

Given the state of affairs in auction theory—there is at least one model, for instance, to support any position one would care to take concerning the revenue of sealed-bid vs. open auctions—it should not come as a surprise that a fair amount of empirical work in auctions is underway. This paper reports the results of some recently completed research. I first discuss papers in which the predictions being tested derive directly from the pure theory of auctions, and then papers in which the predictions arise out of an application of auction theory to a related institution.

## I. Tests of the Pure Theory

I consider here two implications for which we now have a fair amount of empirical evidence: the prediction that sealed-bid and open auctions yield equal revenue for a seller; and the prediction that individual bids in a sealed-bid auction decrease with the number of bidders. These predictions are not, of course, robust across all auction models. It is therefore somewhat brave to speak of testing “auction theory” as if there were one theory giving us one unambiguous prediction. Although much of the empirical work is presented as classical hypothesis testing, it is then probably better to think about that work as informal Bayesian learning that is only guided by the structure common to all auction models (for example, Nash equilibrium for a given number of expected utility-maximizing bidders).

## II. Revenue Results of Open vs. Sealed-Bid Auctions

Implications concerning revenue appear to be the most easily testable predictions of

auction theory; all that is required is a suitable data set. To my knowledge, the best data set available covers U.S. Forest Service sales of contracts for harvesting timber in the Pacific Northwest during 1977. Because of a change in federal law, sealed bids accounted for about half of the several hundred sales in that year; open auctions, the usual procedure, made up the rest.

There has been considerable analysis of this data both within the Forest Service and under contract for the Forest Service. At the best, this work consists of regressions using individual sales as observations, the high bid as dependent variable, and a list of independent variables that includes a dummy variable for auction method, the number of bidders, and several variables controlling for the quality of the sale. The general finding is that sealed-bid auctions yield significantly greater revenue than open auctions (for instance, Walter Mead et al., 1981, report roughly a 10 percent higher price for sealed-bid auctions).

My own work on this data set (1984a) corrects for two problems contained in the earlier findings: first, there was some selection bias in the way the Forest Service chose auction methods; and second, auction theory implies a test for revenue equivalence that is different from simply using one dummy variable to account for auction method.

With respect to the first problem, it became obvious upon a little researching that a correct model for these auctions would be a simultaneous equations model, with one equation—a probit model—describing the auction-choice process, and a second equation determining the high bid conditional on auction method. The fact that certain unobservable variables (for example, firms' timber inventories) affected both auction method and high bid leads to nonzero covariance for the error terms of these equations; estimation techniques will therefore have to be something other than *OLS*.

The second problem with early work concerns how auction method enters the high-bid

\*Amos Tuck School of Business Administration, Dartmouth College, Hanover NH 03755. I thank my dissertation committee, especially John Riley, for academic support, and the Sloan Foundation and Tuck Associates for financial support.

equation. Resolution of this problem required a simple reexamination of some basic assumptions in auction theory. Specifically, theorists always compare revenue for a fixed and known number of auction participants. Upon reflection, this implies—with a positive reserve price—that the actual number of *bidders* is not the variable that the theoreticians have in mind. Indeed, if one looks at data for one-bidder sales, one sees that sealed-bid auctions clearly dominate open auctions. That this says nothing about revenue equivalence follows from the observation that the number of bidders is not an accurate measure of the number of traders as envisioned by theorists. (Actually, this evidence on one-bidder sales supports an implicit assumption of auction theory—that participants in a sealed-bid auction do not learn who has a reservation value exceeding the reserve price before the submission of bids.)

The bottom line is that an accurate high-bid model should account for the number of actual bidders and the number of potential bidders. Furthermore, it is likely that the effect of actual bidders on the high bid will differ across auction methods (thus, calculating expected revenue differences entails taking expected values over both the regression error term and over the number of actual bidders, and classical hypothesis testing for revenue equivalence requires testing that several coefficients are jointly zero).

As it turns out, only the first concern—that of neglecting selection bias—seems to affect the empirical results. Whether or not the number of potential bidders is controlled for, *OLS* estimation suggests an expected high-bid difference (sealed less open) of about \$15 (per thousand board feet) with a standard error of around \$3. I used two alternative methods to correct for selection bias, a two-stage method as suggested by Maddala and full-information maximum likelihood. These methods imply an expected revenue difference of between \$1 and \$6, with a standard error of \$5. For comparison purposes, the overall average high bid is about \$130. Also, the joint hypotheses implied by revenue equivalence cannot be rejected at the 95 percent level.

I also analyzed the data in more detail to check for recognizable subsets where any

difference between the auctions would be particularly pronounced. There are some theoretical results on asymmetry of beliefs and on collusion that suggest certain areas as potential recognizable subsets. The empirical procedure here was to take a variable indicating possible asymmetry or ease of collusion (for instance, the concentration ratio for timber purchase by region was used to measure ease of collusion), and then look at the average residuals from the high-bid equation for varying levels of this proxy variable. If, for instance, open auctions make cartels more stable, then open auctions should underperform sealed-bid auctions, especially where the ease of collusion is low. This will show up as a pattern in residuals.

As it turned out, no recognizable subsets could be found even though several proxy variables were used. My conclusion is that anyone with strong revenue equivalence priors should not be shaken.

### III. Competition and Bid Levels

There has been considerable work showing that high bids, no matter what the auction method, increase with the number of bidders. My work of the previous section is just one example. A more interesting problem is whether individual bids also increase with the number of bidders. The “winner’s curse” suggests they might not: with more bidders, there is more negative information associated with winning the auction (this is only within a common-value context).

The most sophisticated analysis of this question is the work of G. W. Gilley and G. V. Karels (1981). They use data from U.S. offshore oil lease auctions and an estimation procedure that takes into account a problem similar to one I encountered for timber auctions: with a positive reserve price, some traders will not submit bids even though they place positive expected value on the tract. Gilley and Karels show that using data only on observed bids biases the estimates because of usual truncated-error considerations. In a model using individual sealed bids as the dependent variable, correcting for this problem via Heckman’s procedure changes the coefficient on “number of bidders” to significantly negative from significantly posi-

tive under *OLS* estimation. Oil firms seem to understand the winner's curse rather well.

#### IV. Tests of the Applied Theory

I briefly discuss some empirical results based on applications of auction theory to the means-of-payment in auctions, and to the effectiveness and strategies of cartels.

Taking the means-of-payment issue first, several results can be derived concerning the use of stock and cash-stock bids in the market for corporate control. First, if we make independent-preference assumptions for how potential acquiring firms value a target firm, it turns out that stock bidding will yield the target more revenue than cash bidding. Interesting as this may be, it seems difficult to test. If we make additional assumptions concerning private knowledge, however, more easily testable predictions fall out.

For example, if the target has private knowledge on its value, it is simple to show that stock and cash-stock offers alleviate the resulting adverse-selection problem encountered by acquirers. Importantly, however, this holds true only when the target firm is not too small relative to the acquirers—if too small, the stock payment doesn't have the desirable contingent-payment feature. Of course, the reverse holds true when it is the acquiring firms that have private knowledge on their values: then it will be cash which alleviates adverse selection and facilitates trade.

A directly testable prediction is then that stock trades should be seen with greater frequency for transactions where the target is not small relative to the acquirer. Although formal tests have yet to be done, preliminary evidence supports this prediction. Further tests could be done if it were possible to identify transactions by the likelihood of target-side or acquirer-side asymmetry. In general, testing models based on private knowledge in such a direct fashion is sure to be difficult; it would seem generally preferable to devise indirect tests such as the size-based test above. This notwithstanding, there is one piece of evidence that can be interpreted as supporting the model: target firms with high market-value to book-value

ratios are most likely to be acquired in stock transactions (see Willard Carleton et al., 1983). This constitutes supportive evidence if we accept the argument that high market-to-book ratios imply the existence of significant intangible assets, the value of which is inherently highly uncertain and susceptible to private knowledge.

Turning to cartel behavior, the presumption has been around for some time that sealed-bid auctions will make life tougher for a bidder's cartel than will open auctions. Marc Robinson (1983) has formalized this and shown that a sealed-bid auction with reserve price is a seller's best defense against cartels. However, this work is again empirical only to the extent that it gives one reason for the widespread use of sealed bid auctions with a reserve price.

Recent work by Jonathan Feinstein, Michael Block, and Frederick Nold (1985) goes one step further. They show how a bidder's cartel can, in an intertemporal auctions context, extract additional monopoly rents from the seller by bidding in such a way as to affect the seller's beliefs about expected future costs and thereby induce him to sell more contracts now. For instance, by keeping the variance of bids low, the cartel can lead the seller into believing that today's bid is a good estimate of what next period's will be. The implications of the model are supported by evidence from confirmed cartel behavior in auctions of North Carolina highway contracts. Specifically, not only are bids on average low when cartel behavior is present, but bids also vary less.

#### V. Outlook

The outlook for additional statistical work in auctions appears good. New theoretical results are coming out for sequential auctions; these may be testable using data from, for instance, Michigan's open, sequential oil lease auctions. Also, for offshore oil lease auctions and Forest Service timber auctions (sealed-bid), data on the whole distribution of bids can be obtained. Following the lead of Feinstein et al., further theoretical results on bid distributions could be formulated and tested. And last, there is the chance that

somebody will again experiment with different auctions.

# Experimental Development of Sealed-Bid Auction Theory; Calibrating Controls for Risk Aversion

By JAMES C. COX, VERNON L. SMITH, AND JAMES M. WALKER\*

We offer a brief survey of bidding theory in high price auctions, of experimental studies of behavior in such auctions, and of the interplay between the design and results of the experiments and efforts to further develop the theory. Two new series of experiments are reported. The first applies a convex transformation of payoffs in an attempt to induce a lowering of subject bids "as if" the bidders had become less risk averse. The second applies a method for inducing any prespecified utility function (for risky choices) on an individual. We use it to induce "as if" risk-neutral behavior. Both series use baseline control to "calibrate" the hypothesized effect of the procedures on "risk-averse" behavior.

## I. Bidding Theory and its Development under Testing

Early experimental papers testing William Vickrey's (1961) noncooperative equilibrium model of bidding behavior for risk-neutral agents in single unit auctions report the robust result that subjects tend to bid significantly higher than the predictions of the model when the number of bidders is  $N \geq 4$ , but not when  $N = 3$ . (For citations to our experimental-theoretical work, see the references in our 1984 article.) The results for  $N \geq 4$  are consistent with extensions of the Vickrey model which postulate that agents all have the same concave utility for monetary surplus (for example, Charles Holt, 1980). However, these extensions also imply

that all bidders use the same equilibrium bid function:  $b_i(v_i) = b(v_i) \geq b_n(v_i)$ , for all  $i$ , where  $v_i$  is the value of the auctioned item (known only) to  $i$  and  $b_n(v_i) = (N-1)v_i/N$  is the Vickrey risk-neutral bid function when each  $v_i$  is drawn independently from the constant density on  $[0, \bar{v}]$ . We have tested the null hypothesis that the bids submitted by the  $N$  bidders in each experimental group can be regarded as  $N$  samples from the same population. It is rejected in 13 of 23 experimental groups. A straightforward conclusion is that an appropriate extension of the model should be based on the assumption of heterogeneous risk-averse bidders. We have articulated such a model for single unit auctions and extended it to multiple unit discriminative auctions. Experimental tests of the multiple unit model strongly support the interpretation that bidders bid as if they were heterogeneous and risk averse (we reject the hypothesis of homogeneous agents in 24 of 28 experimental groups).

This constant relative risk-averse (CRR) model assumes that (a) each agent  $i$  chooses  $b_i$  to maximize  $EU(b_i) = (v_i - b_i)^{r_i} G_i(b_i)$ , where  $G_i(b_i)$  is the probability that  $b_i$  is the highest of  $N$  bids; (b) agent expectations are rational,  $G_i(b_i) = G(b_i)$ ; (c) each  $v_i$  in any auction is drawn independently from the constant density on  $[0, \bar{v}]$ ; (d) the  $N$  agents are drawn from a population with some distribution  $\Phi(r_i)$  on the characteristic  $r_i \in (0, 1]$ . For single unit auctions, these assumptions imply the inverse equilibrium bid function

$$(1) \quad v_i = (N-1+r_i)b_i/(N-1),$$

for all  $b_i \in [0, \bar{b}]$ ,

where  $\bar{b} = (N-1)\bar{v}/N$  is the maximum bid that would be made by a risk-neutral agent. (The solution for  $b_i > \bar{b}$  has no closed form.) Hence, if any two of  $N$  bidders ( $i, j$ ) have

\*Cox and Smith: Professors, University of Arizona, Tucson, AZ 85721; Walker: Assistant Professor, Indiana University, Bloomington, IN 47401. Financial support by the National Science Foundation (grants SES-8205983, SES-8404915, and SES-8310096) is gratefully acknowledged.

distinct *CRR*A parameters ( $r_i, r_j$ ), a prediction of the model is that in a sequence of auctions  $t = 1, 2, \dots, T$ , the observed bids will identify a distinct homogeneous linear bid function for each bidder whose slope will reveal each bidder's *CRR*A utility parameter.

We have conducted and reported two direct tests of the above *CRR*A model and its multiple unit generalization. The first test applies the following property of *CRR*A utility: a scalar change,  $\alpha$ , in payoffs has no effect on expected *CRR*A utility-maximizing decisions. This is seen in (a) above if we express expected utility in the form,  $EU(b_i) = [\alpha(v_i - b_i)]^{\alpha} G(b_i)$ , where  $\alpha(v_i - b_i)$  is the outcome in U.S. currency for the winning bidder. Since  $\alpha$  affects only the scale of utility it has no effect on the bid function (1). We report paired comparison experiments in which  $\alpha = \$1$  in the control experiments and  $\alpha = \$3$  in the paired treatment experiments. There is no significant difference in the outcomes between paired experiments. Similarly, if  $\bar{v}$  is increased, say tripled, this model predicts the same scalar increase in  $v_i$ ,  $b_i$  and  $v_i - b_i$ ; that is, in (a) we can write expected utility in the form  $EU(\mu_i) = [\bar{v}(v_i - \mu_i)]^{\alpha} G(\mu_i)$ , where  $\mu_i = b_i/\bar{v}$ ,  $v_i = v_i/\bar{v}$ . Hence a scalar change in the  $v_i$  has no effect on normalized bids. We have reported comparison experiments (multiple units) in which  $\bar{v}$  (and each  $v_i$ ) is tripled. The effect is to triple average bids, and the conclusions based on  $\alpha = \$1$  are not altered when  $\alpha = \$3$ .

Since *CRR*A utility is the only utility function with these scalar invariance properties, these experiments provide important independent support for the theory beyond the earlier *ex post* analysis showing that observed bids are consistent with the assumption that agents are risk averse and heterogeneous. The new tests for scalar effects were motivated a priori by the theory.

Two well-known "logical" objections to all *CRR*A utility models are a recurring part of the conventional wisdom connected with expected utility theory (*EUT*), although these objections are devoid of observational support: (A) "*CRR*A utility is unacceptable as it implies that absolute risk aversion grows without bound as  $v - b$  approaches zero";

(B) "The *CRR*A bidding model admits of a tractable solution only if initial wealth is (or can be normalized on) zero."

The a priorist objection (A) asserts that any *EUT* model can be "tested" by examining its absolute risk-averse implications, and that behavior near some boundary (zero) is a crucial test of any hypothesis. This is like arguing (without resorting to observation) that the inverse square law of attraction is falsified, since the force of attraction goes to infinity as the distance between masses approaches zero! For the vast majority of subjects, when  $v$  is near zero, the ratio of bid to value is similar to that for large values of  $v$ ; that is, one observes no peculiarity in bidding behavior near zero, which is predicted by equation (1) based on *CRR*A utility. A small minority of subjects bid either zero or their value, at low values of  $v$ . This "throw away" bid phenomenon can be interpreted as the result of payoffs being so low that it is not worth the trouble of a "serious" bid. Since it is not clear what is "optimal" when payoffs are at *epsilon* levels, other theories such as random or erratic behavior should not be discounted, just as in particle theory (which is disciplined by data) other theories take over in the small.

Concerning objection (B), we have been quite explicit from the beginning in referring to  $v_i - b_i$  as the monetary *income* from an auction. This is because we accept the findings of a vast literature going back at least to Markowitz, and corroborated by Mosteller and Nogee, Davidson, Suppes and Siegel, Edwards, Kahneman and Tversky, Binswanger, and others (see Mark Machina, 1982, for numerous references). Generally this literature supports the relative invariance of risk-taking decision behavior with initial wealth (the "Markowitz hypothesis" of a horizontally shifting utility of wealth). Also, this literature does not find support for constant absolute risk aversion (*CARA*) (Machina, p. 285). *The prize to which EUT applies* (wealth, income etc.) *is a hypothesis separate from the axioms of EUT which do not define that prize.*

Various extensions of the original Vickrey model and of Holt's identical bidders risk-averse model are contained in the literature.

Paul Milgrom and Robert Weber (1982) consider the effect of information. However, given the robust experimental result that bidders bid as if they are heterogeneous and risk averse, these extensions (for first price and Dutch auctions) are based on behavioral assumptions already shown to be inconsistent with the data. Eric Maskin and John Riley (1984) offer a potentially fruitful extension based on the assumption of a one-parameter utility function  $u(-b_i, \theta_i)$ , where  $b_i$  is  $i$ 's bid. If  $\theta_i = v_i$ , we have the case of identical bidders with differing private values, but with the bidding commodity medium distinct from the commodity item being auctioned. If  $\theta_i = r_i$  (any risk parameter), we have heterogeneous risk-averse bidders, but, implicitly, all must place the same value on the auctioned item. Thus the minimum generalization requires a utility function of the form  $u(v_i - b_i; r_i)$  to capture both taste and risk attitude diversity. Cox and Smith (1984) develop an equilibrium bidding model for a utility function of the form  $u(\theta_1 - b, \theta_{-1})$ , where  $(\theta_1, \theta_{-1})$  is an  $M$  vector of characteristics.

## II. Models of Control for the Effect of Risk Aversion

We interpret the observation that subjects bid in excess of the predictions of the Vickrey model as due to heterogeneous risk-averse agents, and have used this *interpretation* to develop an improved model. Subsequently this model was found to be consistent with the scalar invariance tests described above. Now we ask whether direct methods might be applied to examine this risk-averse interpretation of the data. Other interpretations are possible. We might assume in place of (a) that agents choose bids to maximize  $EU(b_i) = (v_i - b_i)G_i(b_i)$ , and instead of (b), that  $G_i(b_i) = [G(b_i)]^{1/r_i}$ , where  $1/r_i$  is now a characteristic of bidder  $i$  that transforms the objective probability of winning,  $G(b_i)$ , into a subjective probability of winning,  $[G(b_i)]^{1/r_i}$ . This subjective expected value (SEV) model is prominent in psychology (see Machina, pp. 290-91). It abandons Muthian rational expectations, but the resulting model yields a bid function identical with (1), and the two theories are observa-

tionally equivalent on the basis of all experimental tests to date. The methodological point is that the parameter  $r_i$  is not observable; it is a construct based on an interpretation of what is driving behavior, and other interpretations are potentially admissible. We have adopted the heterogeneous risk-averse interpretation because it is an integral part of the traditional *EUT*, while the alternative is thought to be "*ad hoc*." This does not mean that *EUT* is "true," but that it appears that there is not yet a sufficient basis for the scientific community to abandon *EUT*.

We propose two payoff manipulation models which, based on *EUT*, should have a determinate effect as interpreted in terms of risk aversion. If these models are "correct," and our interpretation that subjects are risk averse is correct, the new data should be consistent with these predictions.

*Model I.* In a first price auction, if subject  $i$  wins, suppose that instead of paying  $(v_i - b_i)$  dollars to  $i$  we pay  $a(v_i - b_i)^2$  dollars,  $a > 0$ . In the *CRRRA* model it is seen that the problem now is to maximize  $EU(b_i) = [a(v_i - b_i)^2]^{r_i} G(b_i)$  and equation (1) becomes  $v_i = (N - 1 + 2r_i)b_i / (N - 1)$ , for all  $b_i \in [0, \hat{b}]$ , where  $\hat{b} = (N - 1)\bar{v} / (N + 1)$ . Thus if an individual's personal measure of *CRRRA* is  $1 - r_i$ , under the payoff transformation of Model I, that individual will behave "as if" the *CRRRA* measure had changed to  $1 - 2r_i$ . This equation provides strong quantitative predictions of the effect of the transformation. A weaker qualitative prediction is that the individual will bid less under the transformation.

*Model II.* Instead of paying  $(v_i - b_i)$  dollars to the high bidder, suppose we pay the winner  $(v_i - b_i)$  unit lottery tickets. The individual then participates in a lottery in which he/she receives  $x_1$  dollars in U.S. currency with probability  $(v_i - b_i)/\bar{v}$  and  $x_2$  dollars ( $x_1 > x_2$ ) with probability  $1 - (v_i - b_i)/\bar{v}$ . Suppose further that the  $N - 1$  low bidders in the auction all receive  $x_2$  dollars. Since the probability of  $x_1$  is linearly increasing in  $(v_i - b_i)$ , if *EUT* applies to individual behavior this procedure will cause the individual to bid "as if" risk neutral (Alvin Roth and Michael Malouf, 1979; Joyce Berg et al., 1984). To see this, note that bidder  $i$ 's deci-

sion problem is to

$$\begin{aligned}
 (2) \quad & \max_{b_i} \left[ G_i(b_i) \left\{ u_i(x_1) \left( \frac{v_i - b_i}{\bar{v}} \right) \right. \right. \\
 & \left. \left. + u_i(x_2) \left( 1 - \frac{v_i - b_i}{\bar{v}} \right) \right\} + (1 - G_i(b_i)) u_i(x_2) \right] \\
 & = \left[ \frac{u_i(x_1) - u_i(x_2)}{\bar{v}} \right] \\
 & \times \max_{b_i} [(v_i - b_i) G_i(b_i)] + u_i(x_2),
 \end{aligned}$$

which is formally equivalent to Vickrey, giving  $v_i = Nb_i/(N-1)$ , if  $G_i(b_i) = G(b_i)$ .

Berg et al. have generalized this procedure to induce any prespecified preferences, which they proceed to test experimentally using *CARA* and constant absolute risk-prefering (*CARP*) preferences. They provide a qualitative test by soliciting responses to a choice between two bets, *A* and *B*, with the property that the induced *CARA* function implies that *A* is preferred to *B* while the *CARP* function predicts that *B* is preferred to *A*. They report that significantly more than half (88.3 percent) of the choices correspond to the predictions. They also elicit minimum selling prices for bets from the two groups and compare these with the calculated certainty equivalents of the bets. The observed prices reported by the subjects are then compared with those predicted to provide a quantitative test of their model. For both groups they reject the null hypothesis of no relationship between the *average* observed prices and those predicted. However, the average prices from the risk-averse group tended to be systematically biased above the predicted certainty equivalent. Also, the variance of the observed prices was high.

This is encouraging in that it provides evidence favoring the gross predictive implications of inducing known preferences on subjects. The procedure is potentially important in enabling one to (a) control for risk aversion where other aspects of behavior are the primary focus of the investigation (Roth and Malouf), or (b) induce known risk pref-

erences in a market whose behavior is hypothesized to be driven by risk aversion.

To our knowledge this promising procedure has not been test-calibrated in a market context; that is, used to induce particular preferences in a market which yields predictions *interpretable* in preference terms. High price auctions allow one to do this based on the Vickrey risk-neutral special case.

### III. Experiments and Results: Model I, Quadratic Transformation

Twelve subjects participated in three sessions each consisting of 4 bidders. Each session consisted of a baseline sequence (*EIB*) of 20 auctions (12 in session 1) in which each subject was paid one cent for each *PLATO* experimental cent earned,

$$(3) \quad (\text{cash cents}) = (\text{PLATO cents}),$$

followed by a transformation sequence (*EIT*) of 20 auctions in which for each auction cash earnings were calculated using

$$(4) \quad (\text{cash cents}) = 0.02 (\text{PLATO cents})^2.$$

In the *PLATO* instructions for *EIT*, tables and graphs are used to inform the subjects of the payoff implications of this transformation. After the first three sessions were completed, four of the subjects were recruited for a fourth retest session consisting of 20 transformation auctions.

Our initial approach to comparing bidding behavior in *EIT* and *EIB* was twofold. First, we ask whether the mean normalized bid of a subject differs in a transformation experiment from that in a baseline experiment. Since the value realizations from the uniform distribution will differ in the two experiments, if *i* bids  $b_i^*$  when the realized value is  $v_i^*$ , we normalize the bid by subtracting the risk-neutral Vickrey bid,  $b_n(v_i^*)$ . Thus, for each *i* we compute the difference  $D_i = b_i^* - b_n(v_i^*)$  for each auction, giving a set of differences  $\{D_i^B\}$  in *EIB* and a set  $\{D_i^T\}$  in *EIT*. The means  $\bar{D}_i^B$  were positive for all subjects, indicating that all were risk averse in the baseline sequence. Also,  $\bar{D}_i^T > 0$  for all

$i$ , as each subject continues to exhibit risk aversion under the transformation. Furthermore,  $\bar{D}_i^B - \bar{D}_i^T$  is positive for eight of the twelve subjects indicating, as predicted, a shift toward less risk-averse behavior with the transformation. In the retest, session 4, all four subjects bid lower in *EIT* than in *EIB* (one subject had bid higher in the earlier session).

However, this apparently good support for Model I could not withstand deeper examination. The payoffs in (3) and (4) imply that a bid for a profit of less than 50 yields a lower return under the transformation than in the baseline, and vice versa for a bid with potential profit in excess of 50. Aware of this, in advance of the experiments we had conjectured that a "satisficer" might bid relatively lower (higher) in *EIT* at profit levels below (above) 50, as a means of maintaining *EIB* performance in *EIT*. A closer examination of individual bids revealed that this effect was strong, contrary to the predictions of Model I.

#### IV. Experiments and Results: Model II, Lottery Payoffs

Twelve new subjects participated in three sessions, each consisting of 4 bidders and two parts. The first part was a sequence of 20 baseline experiments (*E2B*) with each subject paid one cent in cash for each cent earned in the experiment. The second part consisted of a sequence of 20 auctions (*E2L*) in which subjects in effect earned one lottery ticket for each cent won in an auction. Eight of the twelve subjects were then recruited for two retest sessions, 4 and 5, consisting of 20 auctions with the lottery payoff. The lottery operated as follows: A box containing 1000 tickets, numbered consecutively, was displayed to the subjects. The high bidder in each auction was assigned ticket numbers in an amount equal to the bidders experimental profit in cents. Thus, if the winning bidder had a value of \$8 and bid \$6 when  $\bar{v} = \$10$ , she might be assigned the lottery numbers 1–200. If the ticket she then drew was in the range 1–200, she received a cash payoff of \$7.50. Otherwise, she received \$0.25. All losing bidders received \$0.25 in cash.

Ten of the twelve subjects bid *significantly* "as if" risk averse in *E2B*, but, contrary to Model II, only one of these subjects was induced to bid as if risk neutral in *E2L*. It appears that Model II has one chance in ten of making a correct strong form prediction. This result was not changed for any subject in the retest sessions 4 and 5. A weak form prediction of Model II is that the difference between baseline and lottery mean bids,  $\bar{D}_i^B - \bar{D}_i^L$ , is positive indicating a shift toward risk neutrality. Only six of twelve subjects were consistent with this prediction.

#### V. Conclusions of the Calibration Experiments

Model I, applying a quadratic payoff transformation, predicts a doubling of the "as if" *CRR*A parameter  $r_i$ , or, more weakly, a shift in the direction of lower bids (less risk-averse bidding). The experimental results belie this prediction. A close examination of individual bidding suggests that subjects bid less only when the profit potential is below the 50 cent "break-even" level. Above this 50 cent potential profit level, subjects tend to bid relatively higher. This can be interpreted as a type of "satisficing" behavior in which subjects attempt to do at least as well under the quadratic transformation as in the baseline experiments. Does this test invalidate the *CRR*A model of bidding? No; literally, it questions the *conjunction* of the *CRR*A model with the transformation of Model I. Since the *CRR*A model has performed well in previous tests, Model I should be the immediate focus of deeper examination. In particular, the results suggest the need for a change in design that would eliminate the break-even 50 cent profit defined by the intersection of the baseline and quadratic payoff functions. The predicted result is that the hypothesized satisficing effect will be eliminated. Of course, the theory asserts that behavior should not be affected by this artifact, but one would like to know if the theory does better when the artifact is removed. After all, these are not calculating agents, and it may not be difficult to introduce perceptual distortions that alter equilibrium behavior.

Model II predicts risk-neutral bidding for any subject showing risk-averse bidding in a baseline experiment. Since nine of ten subjects bid significantly above the risk-neutral bid function under both lottery and monetary payoffs, these results do not support the predictions of Model II. Given the generally supportive results of earlier direct tests of the bidding model, the predictive failure of Model II can be interpreted as providing (indirect) evidence against the compound lottery axiom of *EUT* that is essential in Model II. Furthermore, these results may have implications for other research programs that must postulate the behavioral validity of the lottery procedure as a conditional in experimental tests of models that require risk attitude of agents to be controlled.

## Modes of Thought in Economics and Biology

By PAUL A. SAMUELSON\*

Sociobiology, particularly in connection with its obsessive interest in Hamiltonian altruism, has veered closer towards economics. Reactions within economics against highfalutin borrowings of the methodology of mathematical physics led Alfred Marshall and a host of later writers to hanker for a "biological" approach to political economy. A dispassionate audit of what resulted from this urge would have to report a disappointing paucity up to now of fruitful finds or insights.

But independently of this anti-physicism strain in economics there developed within economics an "evolutionary approach." It is not social Darwinism that I am referring to (although an insidious temptation in that direction is sometimes involved). Rather, several writers explored the notion that—what survives under competition, whether in the jungle or the marketplace, may resemble what is achieved in a maximum problem's solution—even though no participants in the struggle may have any perception and awareness that they as individuals are maximizing anything or awareness that the group ends up doing so. Some names associated with this notion are Armen Alchian (1950), Milton Friedman (1953), and Sidney Winter and Richard Nelson (1982). My *Foundations* (1947) discussions of the stability of surviving forms, borrowed explicitly from the physiologist philosopher L. J. Henderson (1917), is somewhat in this same vein.

There is really no trace of anti-physicism in such an approach. Indeed, the case where

soap bubbles unconsciously form the shapes that maximize elaborate integrals in the calculus of variations is very much like the case where leaves and branches of a tree, competing for access to the sunlight, achieve maximal shapes.

When Edward Wilson's manifesto for sociology first came out (1975), I predicted that it would meet a resonant response in Chicago-school economics. Everything has proceeded on schedule to validate my forecast. A hard-boiled economist who shares his income with his child can now cease to feel guilty about this superficial violation of the doctrine of "no free lunch." Hamiltonian inclusive fitness shows that this is just a selfish gene's way of making more of itself—no less respectable a process than that in which I cannily outsell or outproduce my neighbor.

### I. Population as Part of Economics

Population analysis is at the intersection of social science and biology. Once upon a time, throughout the heyday of classical economics, demography belonged to political economy. The supply of labor was one of the important endogenous variables in the systems of Smith, Malthus, Mill, and Marx. I have expressed in many places how superficial and empty the concept of a subsistence wage has always been. Although economies in the pre-industrial revolution era differed widely in their per capita levels of real income, writers blithely embraced the paradigm of a horizontal *SS* supply curve for labor, as if the cost of production and reproduction of labor was an identifiable exogenous parameter. There must be something very tempting about this vacuous notion, since so many different scholars did succumb

<sup>†</sup>*Discussant:* Gordon Tullock, Public Choice Center, Virginia Polytechnic Institute and State University.

\*Department of Economics, Massachusetts Institute of Technology, Cambridge, MA 02139. I owe thanks to the Sloan Foundation for partial support.

to it. And, by the age of Mill and Marx—indeed, even in Ricardo's time and Malthus's later editions—the level of the subsistence wage rate was freed from physiological dimensions and became a dummy variable shot through with conventional standards of life hankered after by (some) workers. At this stage a meaningful false theory had been replaced by a meaningless nontheory that could never be vindicated or rejected by any pattern of historical facts.

## II. Paradigm Lost and Regained

One feature of neoclassical economics that distinguishes it from the classical version is the removal of population as a variable subject to economists' equilibrium analysis. Knut Wicksell, an autodidact in a backwater of northern Europe, was the last neoclassicist to preoccupy himself with demography. Marshall, Edwin Cannan, Frank Knight, and A. C. Pigou all were content to have the trend of population growth imported from the fields of sociology and technical demography. The pioneers of modern demography—Alfred J. Lotka, Robert R. Kuczynski, David Glass, Kingsley Davis, Ansley J. Coale, Nathan Keyfitz, and others—were not primarily economists and made little pretence to be. The classical subsistence wage theory is dead forever—dead as a theory of constancy of wage even as applied to the poor regions of Africa and Asia where gross reproduction rates are still enormously high and where population density perceptibly reduces per capita productivity. So the real wage rate is definitely not an exogenous variable for today's economics. Nevertheless, in recent years economists have begun to infiltrate the field of demography. This is part of the imperialist movement in which we economists try to apply our methodologies to everything—to the law, to the sociology of the family (courtship, marriage, divorce, cohabitation). I have in mind writings by such economists as Richard Easterlin, Paul Schultz, Gary Becker and a whole Chicago school, Ronald Lee, Harvey Leibenstein, and many others.

As might be expected, noneconomists have sometimes resented invasion of their turf.

Demographers are not as titillated as we are by letting the decision to have or not have a child be likened to the decision to buy or not buy a new car. Easterlin aside, the economists' models did not predict in advance the magnitude of the post-1939 baby boom; nor the post-1957 resumption of the trend toward small family sizes. Slutsky-like analysis of the income-and-family size relationship labors like a lion with concepts of *quality* and alternative earning power of spouses, only to produce the mouse that sometimes these days it is fashionable to have 1 or 2 children and sometimes to have 2 or 3. Weak and hard-to-reproduce evidences for extrasensory perception, people find boring. Similarly, a weak tendency for people to have more or to have less of their children during cyclical recessions does not excite noneconomists.

Economists are smart and hard-working people, now being produced in copious supply relative to the traditional problems feasible to make progress on. Like lemmings oppressed by the workings out of the law of diminishing returns, economists will continue to swarm into the area of demography. Hard work and intelligence will get themselves heard, even when somewhat hamstrung by unpromising initial hypotheses and methods. So, in the end, economists' demography will carve out an ecological niche for itself.

## III. Anecdotes and Anecdotes

A Kuhnian expert in the dynamics of scientific schools will observe how sociobiology extrudes into the traditional grounds of the social sciences. Francis Galton, Karl Pearson, and Ronald Fisher sought genetic explanations for differences in performance and class position. Although R. A. Fisher was a genius in genetics and mathematical statistics, his 1930 classic, *The Genetic Theory of Natural Selection*, seems naive in the degree to which he hypothecates a genetic basis for observed differences in behavior. No cogent evidence is given for his views and indeed it is not clear what evidence would be cogent.

We are beginning to identify today, by means of biochemistry and molecular biology, particular diseases with particular sin-

gularities in DNA data. But just how the courage observed in offspring is related to the genes for courage inherited from their ancestors is as yet a completely nonoperational question. The same has to be said of "altruism," "intelligence," "sexuality," and most of the attributes discussed in the final chapters of Wilson. These final chapters, I noticed at first reading, depend largely upon hypothetical anecdotes and case studies. Initially, I thought this a weakness of the material dealing with man and with higher primates, an understandable let down from the higher level of scientific rigor characterizing the earlier chapters dealing with the solid facts of animal and plant biology. But on further examination and reflection, I discovered that much of what goes under the name of natural history involves a similar marshaling of selective anecdotes. Chemistry and meteorology are not like that. And neither is economics. In economics we have data aplenty. Our subject is inexact but we do apply quantitative analysis (statistical and otherwise) to formulate and test our hypotheses. When you read about Volterra's struggle for existence between predators and prey, or Wilson's programs for a genetic-based ethics, you are not in the constrained world of fact and interpretative hypothesis but rather in the imaginative realm of speculative possibility.

To be sure, more and better observations will be made available by future scholars working in this vineyard. But the point to be made is how far away we now are from a satisfactory state of knowledge in these between-disciplines domains.

Rather than belabor these points about realism and relevance, I wish for the rest of the present endeavor to deal with purely deductive matters, to illustrate by some examples involving sex ratios how unlike (and alike) are the deductive paradigms common to economics (and perhaps sociology) and those of sociobiology and genetic demography.

#### IV. Different Moods

There are important differences between a typical genetic process and an economic or

sociological process. Genetic evolutionary selection, as when there is survivability advantage in a malarial environment for the genotype that is heterozygous for the sickle cell trait, involves no consciousness or overt purpose: any teleological aspect is an "as if" phenomenon. Ofttimes genetic change is glacially slow, involving hundreds of generations. So to speak, there is no "action at a distance" in demographic genetics: funeral by funeral, mating by mating, each allele must make its way. By contrast, in economics what one firm innovates to do now can in principle sweep the whole industry by quick imitation.

As a typical process in biology, consider a society that relies solely on the rhythm method for its birth control (a specification already shot through with sociology and convention). Given enough time the strategy will partially or wholly self-destruct—as those genetically disposed to have irregular menstrual cycles leave more of their offspring to be represented in subsequent populations. But the biological time scales involved run into hundreds of years, by which time there will have occurred scores of alternations of sociological ideologies.

The sex ratio is a useful topic for our comparison.

#### V. Balanced Sex Ratio

Human babies are almost as likely to be girls as boys: typically males are in small excess, 106 to 100; but females have lower mortality so that by adulthood the sex ratio is in virtual balance. Animal populations, whether monogamous or not, are observed often to have nearly balanced sex ratios at birth, with whatever unbalance that implies in maturity.

R. A. Fisher gives an ingenious argument why individual natural selection might be expected to evolve toward a balanced sex ratio at birth or conception. Here is my attempt to paraphrase his logic:

Suppose all genetic strains but yours tend to produce an excess of male over female births. If your strain tends to produce a more balanced sex ratio of

births, other things equal, each of you will be better represented with grandchildren than each of the other crowd — this for the reason that, for producing the grandchildren generation, the totality of *all* sons have exactly equal representation with the totality of *all* daughters (even when the respective totals are unequal!), with the implication that each daughter brings you more in relative grandchildren representation than each son does. So, in each generation, the unbalance of the sex ratio at birth tends to be reduced. Only a sex ratio at birth in balance is immune to evolutionary drift.

To see how mathematical geneticists put this heuristic argument on a rigorous analytical basis, refer to I. Eshel (1975), Joel Yellin and myself (1977), and the Gibbs Lecture of Samuel Karlin (1984). To illustrate the logic it suffices for me here to sketch the rock-bottom simplest case.

#### VI. Darwin's Mindless Invisible Hand

Adult male and females,  $[M, F]$  mate to produce this period's births,  $B$ . The fractions  $[g, 1-g]$  determine the breakdown of newborns between males and females. The mortality fractions  $[p_m, p_f]$  specify how many of the newborn males and females survive to be adults in the next period. With mortality specified, our model is complete once we specify the mating-fertility function determining the output of births out of the inputs of adult males and females. I write this as

$$(1) \quad B(t) = M(t)F(t)b[M(t), F(t)],$$

where  $Mfb[M, F]$  is much like the economists' production function, being monotone increasing (and perhaps concave). Examples would be  $cMF/(M+F)$ ,  $cMF/(\frac{1}{3}M + \frac{2}{3}F)$ ,  $cMF/M^{1/3}F^{1/2}$ .

Combine (1) with our mortality and sex-ratio assumptions

$$(2) \quad \begin{aligned} M(t) &= p_m [gB(t-1)], \\ F(t) &= p_f [(1-g)B(t-1)] \end{aligned}$$

to derive an autonomous first-order difference equation determining births and all demographic variables:

$$(3) \quad \begin{aligned} B(t) &= g(1-g)p_m p_f B(t-1)^2 \\ &\times b[p_m gB(t-1), p_f(1-g)B(t-1)] \\ &= \phi[B(t-1)], \quad t \geq 1. \end{aligned}$$

Thus, if  $Mfb[M, F]$  is first-degree homogeneous, we find Malthus-Lotka exponential growth:

$$(4) \quad \begin{aligned} B(t) &= B(0)R^t, \\ B(0) &= M(0)F(0)b[M(0), F(0)] \\ 1 \cong R &= g(1-g)p_m p_f [gp_m(1-g)p_f]. \end{aligned}$$

If both sexes played a symmetric role in the  $Mfb$  function, maximal group fitness would require that any superiority of females in mortality ought to be compensated by having an excess of males at birth  $g > \frac{1}{2}$ . The above Fisherine argument denies that the Invisible Hand of individual selection will lead to this group fitness state, leading instead to balanced sex ratio at birth ( $g = \frac{1}{2}$ ) whatever that implies for unbalance in the adult sex ratio!

Now introduce genetic selection. The old genetic strain that  $(M, F, B, g)$  above belonged to, I now write as  $(M_A, F_A, B_A, g_A)$ . A mutation creates also a new genetic strain, with  $(M_a, F_a, B_a, g_a)$ . (To keep the discussion simplest, I don't deal with diploid inheritance, which would require us to introduce  $[M_{AA}, M_{Aa}, M_{aa}, F_{AA}, \dots]$ , etc.) The axioms of the Fisherine syllogism are very strict:

1. The genotypes differ *only* in sex ratio:  $g_A \neq g_a$ .
2. The same survival fractions  $[p_m, p_f]$  apply to both genotypes.
3. Where fertility-mating is concerned, an individual of genotype  $A$  has *exactly* the same properties as any like-sexed, like-aged individual of genotype  $a$ . This implies random or nonassortative mating and that total

births,  $B = B_A + B_a$ , are determined as before by total  $(M, F)$  numbers:

$$(5) \quad B_A + B_a = (M_A + M_a)(F_A + F_a) \\ \times b[M_A + M_a, F_A + F_a].$$

For short, the last factor on the right will be written as  $b$ .

4. The last axiom specifies that offspring of parents both of the same genotype are of that genotype; half the offspring of parents of different genotype average out to be of the father's genotype, half of the mother's, and sampling irregularities are assumed ignorable in a large enough population.

The axioms translate in a straightforward way to give the following first-order difference equation system determining how the vector  $[B_A(t), B_a(t)] = [B_A, B_a]$  transforms itself into  $[B_A(t+1), B_a(t+1)] = [B'_A, B'_a]$ :

$$(6A) \quad B'_a = \{g_a(1-g_a)B_a^2 + \frac{1}{2}[g_A(1-g_a) \\ + g_a(1-g_A)]B_AB_a\} \{p_m p_f b\}.$$

$$(6a) \quad B'_A = \{g_A(1-g_A)B_A^2 + \frac{1}{2}[g_A(1-g_a) \\ + g_a(1-g_A)]B_AB_a\} \{p_m p_f b\};$$

Suppose we are interested only in ratios of genotypes,  $B_a/B_A = x(t)$ , and in the ratio of the sexes at birth, as measured by  $g(t)$  the properly weighted average of  $[g_A, g_a]$ . We can divide (6a) by (6A) and cancel out completely both any differences in the sexes' mortality fractions and any special features of the  $b[M, F]$  function that happen to obtain!

We then get the autonomous first-order difference equation in  $[x(t), x(t+1)]$ :

$$(7) \quad x(t+1) = x(t) \times \\ \frac{g_a(1-g_a)x(t) + \frac{1}{2}[g_A(1-g_a) + g_a(1-g_A)]}{g_A(1-g_A) + x(t)\frac{1}{2}[g_A(1-g_a) + g_a(1-g_A)]}$$

It can then be shown graphically or analytically that, for  $0 < x(0) < \infty$ , as  $t \rightarrow \infty$  the overall sex ratio  $g(t) \rightarrow \frac{1}{2}$  if  $(g_A, g_a)$  straddle

$\frac{1}{2}$ ; if they are both on one side of  $\frac{1}{2}$ ,  $g(t) \rightarrow$  the  $(g_A, g_a)$  nearest to  $\frac{1}{2}$ .

**Warning:** Balance of the sexes at birth would obtain in this model even if males lived longer than females,  $p_m > p_f$ , and even if females were more important for nurturing and if a small fraction of the available males would suffice for purposes of procreation. Fitness of the *group*, when it calls for balanced sex ratio of adults or such adult unbalance as implies a strong unbalance at birth, will be sacrificed to that maximizing *individual fitness*. Economists understand well that what's good for each may be bad for all sellers—as in Prisoner's Dilemma, or in perfect competition.<sup>1</sup>

## VII. Economic and Sociological Processes

New techniques are making it possible to know in advance what will be the sex of a baby. With knowledge may come power to control. Thus, if one learns by amniocentesis that an embryo is female, and if one prefers a male, an abortion might be decided on. If such customs become common, some far-reaching sociological changes could occur. And these would have economic ramifications.

Nor is all this new. Animal breeders and folklore have held that the probabilities of the different sexes can be affected by timing patterns within the menstrual cycle. Indeed, it is reported in *Too Many Women?* by M. Guttenberg and P. F. Secord (1983) that the

<sup>1</sup>See Fisher (pp. 142–43), W. D. Hamilton (1967), Wilson (pp. 316–17), R. L. Trivers and D. E. Willard (1973), for alternative models that alter conclusions about balanced sex ratios by bringing in considerations of “parental investment” and other interactions between genotype and fertility or mortality functions and parameters. Where an economist would say: “Parents will invest in one sex or the other up to the point of equality of *marginal advantage*,” biologists more often speak of equality of investments in the two sexes. Equality of derivatives and equality of ordinates are not always the same thing! Actually, selection would lead to two-thirds of newborns being male if the  $(M, F)$  symbols in (1)–(7), instead of meaning (males, females), had to be interpreted to be (pairs of males, single females)—as when each female uses up twice the “energy” or “mass” of one male.

Talmudic practices followed by nineteenth-century orthodox Jews of Eastern Europe resulted in a sex ratio as distorted as 146/100. Also, the mystery of the alleged excess of male births occurring in the World War I epoch may even be resolvable by prosaic factors having to do with scheduling of army leaves and discharges during that period.

Whatever the mixture of science fiction and fact characterizing present knowledge, it is not unlikely that better control over gender is just around the corner for reasons that have nothing to do with genetic change. How do economists model such a process? I shall deal only with an archetypal example.

Scarcity tends toward value. The more women there are, other things equal, the lower might be expected to be their relative wages and lifetime earnings. Feminists might therefore look with some approval upon a future trend toward more sons rather than daughters.

Working against this in the political sphere is that scarcity leads to weakness of voting position and respect. "Expand thy numbers," is the injunction each identity group responds to. Here I shall stay with the economist's case where per capita real incomes are hurt by abundance of numbers.

The simplest case is where the real national product,  $Q$ , is produced by the male and female adult labor forces,  $(M, F)$ , with the imputed real wage to each being determined by respective marginal products:

$$(8) \quad Q = Q[M, F] = Mq[F/M], \\ q' > 0 > q'';$$

$$W_m = \partial Q[M, F] / \partial M = q'[M/F];$$

$$W_f = \partial Q[M, F] / \partial F = \phi(W_m), \quad \phi' < 0.$$

*Warning:* a polar feminist model that supposed male and female inputs to be identical factors of production would make  $Q$  be  $c(M + F)$  and necessitate qualifying much of the following analysis.

If some people indulge a strong enough preference for sons, that will skew the adult sex ratio upward, tending to raise female wage rates and lower male rates. If women

are no less productive than men, in the sense that  $Q[M, F]$  is a symmetric function equalling  $Q[F, M]$ , then the female wage will exceed the male. Such an elevation in relative remuneration may serve *partially* to reverse the sex ratio imbalance.

One past reason for preferring sons may have been their superior earning power. Although daughters may perhaps be counted on to be more nurturing to you in your old age, sons may have the greater wherewithal to support you. Or the vanity of having the family name carried on may, under our patriarchal culture, be better served by sons. But now that the contrived scarcity of females raises their earnings, you have a new economic motive to indulge your preference for males less.

The new equilibrium, under the postulated symmetry of  $Q(M, F)$  and specified preference bias toward males, will be toward an excess of males but an excess limited by their induced impoverishment. The approach to the new equilibrium could involve successive over- and undershoots (as in the economist's "cobweb" model, where each person doesn't realize how many others are also doing the same thing). Or the approach may be gradual in the fashion of adaptive expectations. To keep up with the latest fad, we could even fabricate a rational expectations model: in it, people make a best guess about what the future development of the sex ratio will be; they take account of what is implied by this for relative earnings of their sons, daughters, grandsons and granddaughters, and in terms of this make their decisions; and, miracle of miracles, when all do this they together contrive what it is that they each expect.

Again we discover the possibility of a conflict between *group* (economic) selection and *individual* (economic) selection. If two unfriendly societies compete, the more prosperous one (Sparta) may eliminate the other. However, the  $M/(F + M)$  ratio that maximizes total  $Q$  (of Athens) may not be the sex ratio that best pleases its representative citizen. So each following self-interest may achieve the destruction of all.

*Observation:* genetic evolution can work to offset economic unbalancing of the sex ratio. To see this best, suppose  $p_f = p_m$  and

that only a subset of the population exercise gender control by abortion or otherwise. The groups who do and do not control gender need not be genetically defined. None the less, the dynamic Equation (7) could still apply, provided only we can suppose that when both parents belong to one group, so will the offspring. And that when the parents belong to different groups, half the offspring will be like one parent and half like the other.

What will follow? The Fisher logic will then apply to this non-particulate-inheritance setup. With what result? Our defined process of sociological selection will lead to a rebalancing of the sexes! Indeed, the process can lead to a serendipitous balancing if there are two groups, one favoring sons and one daughters: each can then get their heart's desire, with their numerical weightings evolving to keep the overall birth ratio in balance though no one is aware of the equilibrating process.

Mere deduction cannot prove anything definite about real world sex ratios. If we alter the razor's-edge symmetries of the Fisherine premises—admit nonrandom matings, etc., etc.—we of course can no longer deduce balanced sex ratios. Realistic economic models are not too likely to honor the precise “other things equal” premises implicit in the Fisherine deduction.

#### VIII. Finale

There is much territory between economics and biology that is still virgin ground. It will be tilled increasingly in the future. We should not be surprised if the first explorations are both crude and pretentious. Wisdom and maturity are the last settlers to arrive in pioneering communities.

# The New Economics of Labor Migration

By ODED STARK AND DAVID E. BLOOM\*

Research on the economics of labor migration has undergone an exciting and significant transformation during the past few years. At a theoretical level, migration research has expanded the domain of variables that seem to impinge upon and are affected by spatial labor supply decisions; it has highlighted the role of wider social entities and interactions within them in conditioning migration behavior; it has identified new linkages between migration as a distinct labor market phenomenon and other labor market and nonlabor market phenomena; and it has contributed to our understanding of the processes of economic betterment and development. At an empirical level, recent work on the economics of labor migration has confirmed the usefulness of old and well-established models of labor migration. It has also provided better estimates of key behavioral parameters, many of which are important ingredients in ongoing debates over public policies relating to migration. With such an impressive score, it is a wonder that more of the profession has not shifted into migration research. Perhaps this has to do with lack of information.

Our goal here is to summarize the actively evolving ideas, findings, and difficulties in the economics of labor migration. We do this mainly by illustrating selected theoretical and empirical developments which we believe to be on the frontier of research in this area. We also identify several new research topics

that comprise part of the next research frontier. Prior to proceeding with these tasks, we wish to point out that much of the more interesting recent research is associated with migration within and from developing economies. This situation might be partly explained by the fact that the impact of wage differentials on migration tends to be offset by unemployment compensation programs and other fiscal policies in the developed economies. The LDCs' scene thus constitutes a good migration research laboratory for studying migration in general.

## I. Theoretical Issues

Whereas owners of production inputs or commodities, such as bricks or bottles of wine, can ordinarily ship them away (so as to maximize profits or utility) while themselves staying put, owners of labor must usually move along with their labor. Furthermore, owners of labor have both feelings and independent wills. Indeed, most aspects of human behavior, including migratory behavior, are both a response to feelings and an exercise of independent wills. These simple observations divorce migration research from traditional trade theory as the former cannot be construed from the latter merely by effecting a change of labels.

People engage quite regularly in interpersonal income comparisons within their reference group. These comparisons generate psychic costs or benefits, feelings of relative deprivation or relative satisfaction. A person may migrate from one location to another to change his relative position in the same reference group, or to change his reference group. Membership in a low relative deprivation reference group may be well preferred to membership in a high relative deprivation reference group even if in the former a person's absolute income is lower. In general, a person who is more relatively deprived can be expected to have a stronger incentive to

\*Departments of Economics and Population Sciences, Harvard University, Cambridge, MA 02138 and Department of Economics, Bar-Ilan University; and Department of Economics, Harvard University, Cambridge, MA 02138, respectively. Comments by participants in the Harvard-MIT Research Seminar on Migration and Development are gratefully acknowledged. Bloom's research was supported by NIH Grant No. HD18844-02. A longer version of this paper, which includes references, is available from the authors upon request.

migrate than a person who is less relatively deprived. Moreover, a reference group characterized by more income inequality is likely to generate more relative deprivation and higher propensities to migrate. Note also that as particular individuals migrate, the relative deprivation perceived by nonmigrants may change, thereby creating second-round inducements to migrate. For example, if relative deprivation is gauged through a comparison with a reference group statistic such as average income, migration by low-income (i.e., relatively deprived) individuals will cause this statistic to increase and thereby induce migration by other individuals who become increasingly relatively deprived.

Not only can the migration behavior of individuals be expected to differ in accordance with their perceived relative deprivation, it can also be expected to differ according to their skill levels. This outcome results when the assumption of heterogeneous workers is paired with the assumption of imperfect skill information on the part of employers. To obtain some strong illustrative results, consider the following polar case. In a given profession, workers with skill  $S$  receive wages  $W_P(S)$  and  $W_R(S)$  from employers at  $P$  and  $R$ . Assume that skill follows a uniform distribution along a unit interval, that the functions  $W_P(S)$  and  $W_R(S)$  are nondecreasing and linear, and that  $S$  is known by  $P$  and  $R$  employers. Assume further that for low levels of  $S$ , say  $S < S^*$ ,  $W_P(S) > W_R(S)$ , whereas for  $S \geq S^*$  the reverse inequality holds. Clearly, the lowest-skilled workers will not wish to migrate. Assume now that  $R$  employers cannot observe the true skill level of individual  $P$  workers (i.e., that skill information is asymmetric), but that they know the distribution of  $S$  and will pay migrants from  $P$  a wage that is equal to the average productivity of the migrant group. The interior solution  $S^*$  now vanishes and is replaced by one of two corner solutions: there is either no migration at all, or there is migration by all. This result follows essentially because the highly skilled workers who migrate under perfect information may not do so if the pooled wage is too low. But if they do not, the pooled wage is lowered so that the next highly skilled group

also does not find it advantageous to migrate, and so on.

Just as it is clear that neither a brick nor a bottle of wine can *decide* to move between markets, so should it be equally clear that a migrant is not necessarily the decision-making entity accountable for his or her migration. Migration decisions are often made jointly by the migrant and by some group of nonmigrants. Costs and returns are shared, with the rule governing the distribution of both spelled out in an implicit contractual arrangement between the two parties. For example, one important component of the direct returns to the nonmigrating family from the migration of a family member are his or her remittances. Theory suggests the view, that empirical evidence seems to support, that patterns of remittances are better explained as an intertemporal contractual arrangement between the migrant and the family than as the result of purely altruistic considerations.

Theory also offers reasons for the migrant and the family to enter voluntarily into a mutually beneficial contractual arrangement with each other—rather than with a third party—and identifies conditions under which the contract is self-enforcing. Since the chosen contractual arrangement reflects the relative bargaining powers of the parties, this approach can also be used to generate empirically falsifiable predictions about remittance patterns, that is, that variables that enhance the bargaining power of the family and the importance of its support (such as a high-unemployment urban labor market) will *positively* influence the magnitude of migrant-to-family remittances. Note that this approach demonstrates the efficiency, flexibility, and what we might call the dynamic comparative advantage of the family. In other words, it does not view the family as an entity that is split apart as its independence-seeking younger members move away in an attempt to dissociate themselves from familial and traditional bondage, regardless of the negative externalities thereby imposed upon their families. Moreover, this approach shifts the focus of migration theory from individual independence (optimization against nature) to mutual interdependence (optimi-

zation against one another), that is, it views migration as a "calculated strategy" and not as an act of desperation or boundless optimism.

Risk handling provides another illuminating example in which a wider social entity is collectively responsible for individual migration. Clearly, the family is a very small group within which to pool risks. But the disadvantages of small scale may be made up by an ability to realize scale economies yet remain a cohesive group. Such scale economies are achieved by the migration of one or more family members into a sector where earnings are either negatively correlated, statistically independent, or not highly positively correlated with earnings in the origin sector. Again, as in the remittances example, the important point to note is that *both* parties are better off due to migration since, in this case, an exchange of commitments to share income provides coinsurance. Note, in addition, that just as it explains migration by part of the family, this example also accounts for nonmigration by the remainder.<sup>1</sup>

The nature of intragroup interaction could also help to explain features of the economic performance of migrants. To begin with, migrants often outperform the native born in the receiving economy. (We say more on this in Section II.) In addition, heavy reliance upon "network and kinship capital" is another prominent characteristic of migrant behavior patterns. The latter may explain the former quite readily in the context of an economy with a large number of agents whose transactions are governed by a prisoner's dilemma super game. Briefly, a migrant who offers to cooperate in his trade with *anyone* in the first game, whereas thereafter the choice in each game is that of the other agent in the previous game, will tend to be better off than a native who never behaves cooperatively, provided a sufficiently high propor-

tion of trades by migrants are conducted among migrants. This result provides an interesting explanation for the observation that new migrants are assisted by those who have migrated earlier; one good way of having a higher proportion of all trades conducted among migrants when there are few of them is to have additional migrants. The arrival of new migrants confers benefits upon the earlier migrants. It also suggests a resolution to the apparent inconsistency of altruistic behavior within a small group (say, a family) and selfish behavior within larger groups (say, a marketplace); the same strategy, viz, cooperate in the first game, thereafter reciprocate, is systematically applied throughout.

This appeal to strategic behavior may also be used to derive further migration-related insights. Consider, first, a not-atypical village economy in an *LDC* where farming landlords are in an oligopsonistic position with respect to the determination of wages and employment. Through collusion, the farmers can increase their profits. However, labor migration can constitute a credible counter-strategy to this possibility, provided that, from time to time, some undertake it. Note that once again, migration confers benefits upon those who stay behind, in addition to those associated with a leftward shift in the supply curve of labor. Second, consider the case of employers who, in static and dynamic contexts alike, are better off with a larger labor pool than with a smaller labor pool. Since a large labor pool can be developed by cultivating an image of worker success, it might be worthwhile for employers to create high-paying jobs in order to attract more migrants. As long as a large number of workers have the belief that high-paying employment can be obtained, or that it is worth waiting for, a migratory response will be produced. High "institutionally determined" wages in urban labor markets in *LDCs* are thus not necessarily externally imposed upon reluctant employers by government legislation and trade unions. Instead, they may result from endogenously determined strategies designed to maximize profits in dynamic settings. Also, generating few very high-paying jobs and heavily advertising, so to speak, the rewards associated with them may help

<sup>1</sup>The insurance attribute of migration applies to the individualistic case too. For example, just as general human capital provides self-insurance, so does migration in conjunction with specific human capital. Thus, in easing risk bearing associated with investment in specific human capital, migration facilitates such investment thereby conferring efficiency gains.

to maintain a large labor pool in the presence of high levels of unemployment. This strategy will tend to confuse migrant calculations, which may suggest that expected urban income is less than rural income. Thus, high-paying jobs might also be created *in response* to high levels of unemployment rather than preceding them and bringing them about.

Since the endowments and preferences of economic agents are always heterogeneous in practice, selectivity, as such, in response to a given set of prices and opportunities and changes in it, by way of migration or otherwise, is quite obvious. In many cases, whether migration selectivity prevails is not as interesting as the extent to which the migration response diffuses. Indeed, migration can be looked upon as a process of innovation adoption and diffusion. As time goes by, what proportion of a given group of *potential* migrants have migrated? To illustrate, assume there are a number of migration destinations and that there is some prior belief that one particular destination is better than the others. In this setting, the experience of actual migrants provides valuable information that presumably reduces future uncertainty of the remaining pool of potential migrants. Under these circumstances, the most interesting research issues relate to the determination of the speed of adoption of migration as an innovation and the characteristics associated with the delay in the adoption of the innovation (rather than whether it takes place), that is, why are some individuals quicker to migrate than others? For the case of rural-to-urban migration in *LDCs* where, if history were to repeat itself, most rural people will end up as migrants, such an approach seems particularly appropriate. Note that as with a demonstration effect in the case of innovation adoption, a stock of past migrants at a given destination (particularly a large stock) represents evidence that might lead to an upward revision of beliefs that migration is a worthy investment. Moreover, the impact of migration upon the society from which it takes place is now stage-specific. Thus, the divergence of views concerning the consequences of migration (for example, its impact upon the distri-

bution of income by size) can partly be attributed to the simple fact that the underlying observations are made at distinct stages of the diffusion process.

## II. Empirical Considerations

Recent empirical research on the economics of labor migration has benefited a great deal more from the development of new econometric techniques than from new theoretical ideas. The techniques that have substantially improved our ability to use micro data sets in the estimation of relatively standard models of labor migration include techniques for the analysis of qualitative dependent variables, techniques that correct for sample selection bias, and techniques for the analysis of longitudinal and pseudo-longitudinal data. At the micro level, most empirical studies have attempted to test simple microeconomic models of migration according to which individuals (or families) make locational decisions primarily by comparing their income opportunities at alternative locations. The key feature of recent studies of this type is their focus on the estimation of structural, as opposed to reduced-form, models of the migration decision. In the past, a major problem that made the estimation of such models difficult was the absence of data on the wages that particular individuals would receive at two or more locations at the same point(s) in time. In other words, survey data sets typically provide researchers with information on the wages received by individuals at their residential location at the time of the survey, their migrant or nonmigrant status at that location, and selected individual characteristics (for example, age, education, and marital status). To the extent that particular *unobserved* characteristics of individuals are rewarded differently at different locations, the average wage of individuals (conditional on their observed characteristics) at location *A*, who migrated there from location *B*, will provide a biased estimate of the wage that individuals who remained at location *B* would receive if they moved to location *A*.

Largely as a result of advances in the statistical analysis of selected samples, however, we now have fairly simple methods that

we can use to test and correct for the bias associated with this unobserved wage problem. To date, estimates of these structural models of labor migration uniformly support the hypothesis that individuals respond to income incentives in making decisions to migrate. However, further application of these models is desirable, using different data sets and more carefully formulated and tested empirical specifications. It would be interesting to examine whether the strength of the migration response to wage differentials decreases over time, while the response to variables such as relative deprivation increases. We would also like to point out that longitudinal data may prove particularly useful in analyzing the determinants of migration, insofar as they permit a distinctly different approach to the problem of sample selection (i.e., longitudinal data permit researchers to control more directly for unobserved variables that affect wages and that are correlated with the migration decision).

Furthermore, much empirical research has been conducted on the labor market progress of migrants, with special attention paid to the behavior of international migrants. To date, most studies of this topic have involved the estimation of cross-sectional wage equations in which "years since migration" is entered as an independent variable and its coefficient is interpreted as a measure of migrant progress. Typically, these studies find that migrant workers earn less than native-born workers with similar characteristics during the first few years after migration but more thereafter. It has been suggested, however, that this longitudinal conclusion, based on analyses of cross-sectional data, may be an artifact of either the declining quality of migrant labor over time (i.e., a vintage effect) or the outmigration of the least successful migrants. In view of the contradictory nature of extant empirical conclusions, and given the academic and policy importance of this issue, additional research on the pace of migrants' labor market progress is clearly needed. Further analysis of longitudinal data on migrant earnings would also be helpful.

In addition to the two focal points for empirical work discussed above, there are four other areas that empirical economists

have touched upon and which we think should receive further attention. The first of these areas involves estimation of the macroeconomic effects of migration. There is a surprising lack of empirical work on the effects of labor migration on wages and employment in net-sending and net-receiving locations, especially for different types of labor (for example, skilled and unskilled labor). Further work on this topic would be of interest, perhaps involving estimation of the wage and employment effects of migration in the context of well-defined structural models of equilibrium and disequilibrium labor markets. Analysis of the distributional impacts of migration and the degree of substitutability between international and internal migration in the process of labor market adjustment would also be helpful.

Second, the microeconomic and macroeconomic relationships between aging and labor migration are topics which have received only scant and indirect empirical attention (for example, age is usually a right-hand side variable in microeconomic studies of migration decision making). Indeed, empirical evidence strongly suggests that older workers are less mobile than younger workers. This finding is quite plausible for a variety of reasons relating to the differential preferences and opportunities of older and younger workers. It therefore seems likely that workforces in many low-fertility countries will show a declining propensity to respond to exogenous economic change by migration as they age over the next two decades. Thus, to the extent that mobility is one of the key requirements for economic efficiency, it would be useful to know more about the extent to which the aggregate migration behavior of a population is influenced by its age distribution and the underlying bases for this relationship. Such information could be very helpful in debates over public policies that provide incentives to migrate.

The third topic that deserves further empirical attention is the migration behavior of dual-earner families. In its most general form, this issue relates to the broader one of the appropriate unit of analysis for studying migration behavior to which we alluded in Section I, that is, the individual or the family.

# New Evidence on the Timing and Spacing of Births

By JAMES J. HECKMAN, V. JOSEPH HOTZ, AND JAMES R. WALKER\*

This paper is a first progress report of an ongoing empirical study of the determinants of life cycle fertility (see our 1985 paper for a more complete report). At this stage, our analysis is decidedly empirical. Unlike many other areas of knowledge in economics and social science, there are few widely accepted or carefully confirmed "stylized facts" in fertility dynamics to guide economic model builders. This vacuum has inhibited the successful development of economic models of fertility dynamics. The main objective of the early stage of our work is to codify the "facts" in a coherent statistical framework that provides the duration data analogue of the conventional simultaneous equations model.

The starting point for our analysis is the demographic literature. This literature finds that the age at marriage, the occurrence of births inside or outside of marriage, the age of the first birth and/or the durations of previous birth intervals significantly affect the timing of subsequent births over the life cycle. Studies of *marital fertility* by L. Coombs and R. Freedman (1970), L. Bumpass, R. Rindfuss, and R. Janosik (1978), J. Trussell and J. Menken (1978), F. Finnas and J. Hoem (1980), and Hoem and R. Selmer (1984) find that the younger the woman's age at marriage, the more rapid the pacing of subsequent fertility, and that those who begin childbearing early in their reproductive careers subsequently have children more rapidly.

Recent cross-country comparisons of data from the World Fertility Survey have found that the timing of marriage and the lengths

of prior birth intervals directly affect the spacing of subsequent life cycle fertility. Such results have lead G. Rodriguez et al. to conclude that "birth interval lengths depend little upon birth order, but far more upon the length of the previous interval" and that the human "reproductive process can be encapsulated as an engine with its own inbuilt momentum whereby early behavior and socio-economic differences fundamentally determine (along with ageing and secular variation) the remainder of the childbearing experience" (1984, p. 5). Such a view suggests: 1) that the age of entry into marriage (or marriage-like unions, such as cohabitation) and/or the entry into parenthood are the crucial determinants of life cycle fertility and that the variation in completed fertility across the population comes primarily in these initial decisions; and 2) that subsequent childbearing is largely determined by initial events and by the lengths of preceding birth intervals. Another widely held view is that after the first birth interval, subsequent birth intervals are biologically determined until the birth process terminates.

One objective of our study is to investigate the robustness of these findings in other data sets. For a sample of Swedish women described below, we find that the conventional demographic view of the fertility process is largely confirmed on fresh data. The main objective of our study, however, is to probe the empirical findings to discriminate between "structural" and "spurious" explanations for the observed empirical regularities. As is the case in any empirical study, only a subset of plausible determinants of life cycle fertility is observed. Evidence that lagged dependent variables affect current values of those variables or evidence that initial outcomes of a life cycle process affect later outcomes may be due to serial correlation in unobservables.

In the context of fertility, one might expect a woman who desires children or who

\*The University of Chicago and The Economics Research Center/NORC, Chicago, IL 60637. We thank George Yates for his help. This research was supported by Grant No. HD 19226 from the National Institute of Child Health and Human Development.

has a comparative advantage at the activity of child rearing might marry earlier, have children at an earlier age, and invest in household capital relative to a woman with a stronger motivation for market activity. Failure to control for unobserved propensities and skills may explain the regularities noted above. On the other hand, the observed empirical regularities may be the outcome of genuine behavioral influences of past events on current constraints or preferences. For example, early childbearing may cause a woman to invest less in market skills and more in nonmarket skills, leading to higher fertility rates for such women. Our study attempts to shed light on the issue of the causal significance of these demographic empirical regularities. A main conclusion is that controlling for unobservables in a robust nonparametric fashion vitally affects the sign and statistical significance of the estimated effect of early life cycle events on subsequent fertility outcomes. Some of the stylized facts of the demographic literature are not robust to controls for unobservables but others remain.

We find that for a variety of empirical specifications of the life cycle birth process and for a variety of samples that do and do not condition on marital status, in models that do not control for unobservables, the longer a preceding birth interval the longer the subsequent one. Thus, our data exhibit the "engine of fertility" phenomenon noted by demographers. Controlling for unobservables, the "well-noted empirical regularity" either vanishes or reverses in sign. For married women, it vanishes entirely. For a sample of all women in a model that controls for marital status as a covariate, controlling for unobserved heterogeneity produces a "reverse engine of fertility" phenomenon: the longer the preceding birth interval the *shorter* the subsequent one. For a sample of married women, the importance of the age of marriage on the spacing of birth intervals is considerably reduced in size and statistical significance. For a sample of all women, controlling for unobserved variables eliminates the impact of age at marriage on all but the final birth transition.

## I. The Data

The data used in this analysis are from a survey of retrospective interviews conducted by the Swedish National Central Bureau of Statistics in 1981. The survey asked for complete cohabitational, marital, childbearing, and work histories as well as background information of almost 5,000 Swedish women randomly selected from five recent cohorts of women of all marital statuses. (For further description of the data set, see Hoem and B. Rennermalm, 1982.) We have restricted our analysis to a sample of women who were born between 1941–45. For this cohort, we had useable data for 990 women. In order to analyze the effects of sample conditioning in previous studies of marital fertility, we also estimated some models described below on a subset of women from this cohort who: (a) were married at least once prior to 1981, (b) experienced their first "union" (i.e., marriage or consensual union) before age 25, and (c) did not have a birth prior to their first marriage. There are 570 such women.

## II. The Model

For the sake of brevity, we only sketch the statistical model used to perform the empirical work reported below. A full description of the model is available in our companion paper. The main building block is the multistate hazard rate:

$$(1) \quad h_{ij}(t_{ij} | \mathbf{x}'\beta_{ij}, c_{ij}\theta),$$

where  $i$  denotes the origin state and  $j$  denotes the destination state,  $t_{ij}$  is the duration in state  $i$  which exits into state  $j$ ,  $\mathbf{x}$  is a vector of (possibly time varying) observed variables that may include lagged durations or occurrence times of previous events,  $\beta_{ij}$  is a vector of associated coefficients,  $\theta$  is a scalar unobservable, and  $c_{ij}$  is a transition-specific factor loading. Specifying the functional form for the hazard and using the nonparametric maximum likelihood estimation procedure of Heckman and B. Singer (1984b), it is possible to consistently estimate the parameters of the hazard (including the

$c_{ij}$ s) and the population distribution of the unobservables. Allowing the  $h_{ij}(t_{ij})$  to be a nontrivial function of duration  $t_{ij}$  allows for spell-specific duration dependence. For a further discussion of multistate models, see Heckman and Singer (1984a).

A birth process specializes the model to transitions among successive birth states,  $i = 0, \dots, I$ , where  $I$  is the maximum number of births. In this specification,  $j = i + 1$  for each  $i$ . In the restricted birth process model, transitions among marital states are treated as changes in exogenous variables (changes in elements of  $\mathbf{x}$ ). Note that each duration is permitted to be governed by different parameters to explicitly allow for different birth order duration dependence and effects of the  $\mathbf{x}$ 's. Below, we test whether or not the set of parameters are significantly different for the intervals between the second and third births to examine the finding in Rodriguez et al. of no-birth-order effects on higher-order birth intervals. Finally, we note that because women are followed from the age of menarche, there is no problem of initial conditions. (See Heckman and Singer, 1984a, for a discussion of this problem.) In a more general multistate process, it is possible to introduce transitions among birth and nonbirth states. Specifically, in our companion paper, we permit transitions from the single or cohabiting state to the states of marriage and cohabitation, transitions among all three of these states and transitions to births from all possible states.

The empirical results reported below are based on a flexible model with linear and quadratic duration terms:

$$(2) \quad h_{ij}(t_{ij}|\mathbf{x}'\beta_{ij}, c_{ij}\theta) = \exp(\gamma_{0ij} + \gamma_{1ij}t_{ij} + \frac{1}{2}\gamma_{2ij}t_{ij}^2 + \mathbf{x}'\beta_{ij} + c_{ij}\theta).$$

### III. Empirical Results

The variables utilized in our analysis are defined as follows: *DURATION* = number of months/100 spent in current spell; *DURATION*<sup>2</sup> = the square of the number of months/100 spent in current spell; *AGE-*

*UNION* = the woman's age (in months/100 since her thirteenth birthday) at which she first entered either marriage or a consensual union; *AGEMAR* = the woman's age (in months/100 since her thirteenth birthday) at which she was married, if she married, and 0 otherwise; *EVERMAR* = a dummy variable = 1 at the age she gets married and = 0 prior to that age; *AGECOH* = the woman's age (in months/100 since her thirteenth birthday) at which she first cohabitated, if she cohabitated, and 0 otherwise; *EVERCOH* = a dummy variable = 1 at the age she begins cohabiting and = 0 prior to that age; *BIRTHDUR1* = the duration in months/100 of the first birth (for the ever married subsample it equals age at first birth—age at first union and for the full sample it equals number of months/100 since her thirteenth birthday); *AGE1STBIR* = age at first birth in months/100 since her thirteenth birthday; *BIRTHDUR2* = the duration in months/100 from first birth until the second birth; *LFP* = a time-varying variable = 1 if the woman is working at the current duration and 0 otherwise; *EDUC* = a time-varying = 1 if the woman is in school at the current duration and 0 otherwise; *URBAN* = a dummy variable = 1 if the woman grew up in an urban area of Sweden and 0 otherwise; *WHITECOL* = a dummy variable = 1 if the woman's father had a white-collar occupation when she was growing up and 0 otherwise; *UNIV* = a dummy variable = 1 if the woman attended a university by the time of the interview and 0 otherwise.

Table 1 reports empirical estimates of the parameters of parity specific hazard functions for *ever married* women. Panel A reports estimates for a statistical model that does not control for unobservables; panel B reports the estimates controlling for unobservables.

Panel A is largely consistent with the engine of fertility story. The age of first union (marriage or cohabitation) is positively associated with the age of first birth and negatively associated with the durations of subsequent births. The length of the previous birth interval is positively associated with the length of the subsequent interval. (This is so

because a negative effect of preceding duration on a current hazard means the transition rate to the next child is smaller for the next duration and hence the interbirth interval tends to be larger.) Background variables such as father's occupational status play a minor role.

Controlling for unobserved heterogeneity using a nonparametric maximum-likelihood procedure causes the effect of length of the preceding birth interval on current transition rates to vanish. In fact, for the latter two transitions, the estimated effect of lagged births switches sign. The effect of age at marriage on the estimated transition rates becomes *stronger* for the transition to the first birth and for the transition from the second to the third birth. The fact that unobservables are empirically important is reflected in the great improvement in the fit of the model to the data as measured by the log likelihood.

Table 2 reports empirical estimates for a sample of all women irrespective of their marital history. The new explanatory variables reported in that table are introduced to control for marital history. Such "controls," while traditional, are *ad hoc*. In our companion paper, we estimate a multistate model that breaks out transitions from each marital state to fertility and allows for endogenous transitions among marital and fertility states.

Controlling for heterogeneity in a model estimated on this sample of women causes the effect of age at marriage to vanish from the model (except for the last transition) and causes the effect of the length of the preceding interval on the transition rate to the next birth to reverse sign. *For the full sample of women, the engine of fertility works in reverse.* Controlling for unobservables, a long first birth interval leads to a short second birth interval and a long second birth interval leads to a short third birth interval. These results are consistent with a fixed target model of fertility in which a delay in the arrival of one child is compensated for by an acceleration of the rate of arrival of the next child.

The hazard functions reported for both samples control for the woman's current labor force participation and school atten-

dance statuses as covariates. While some of the studies cited above include these variables, it may be argued that they are endogenous variables. In results not reported here, we reestimate the model excluding these two variables. Our conclusions are not changed when they are omitted.

The main point to extract from our analysis is the fragility of the "empirical regularities" to the introduction of unobservables. The "stylized facts" currently offered by demographers do not recognize the importance of unobservables. It would be unfortunate if economists were to take as their mission the formulation of economic models to explain phenomena generated by the simple fact that people are different.

An encouraging feature of these empirical results is that, for the Swedish data, we decisively reject the "biological determination" view that higher parity hazards are identical. Controlling for heterogeneity that could lead to spurious differences in parity specific hazards even if the conditional hazards (given the unobservable) were equal across parities, we reject the hypothesis that the transition rate from the first to the second birth is identical to the transition rate from the second birth to the third birth. The  $\chi^2$  statistics for the hypothesis that the corresponding coefficients of these two transitions are the same are: 581.9 with 11 degrees of freedom for the ever married sample of women and 351.0 with 14 degrees of freedom for the full sample of women.

#### IV. Conclusions

Our results demonstrate the importance of controlling for unobservables in the analysis of life cycle birth processes. We conclude this paper by noting an additional issue that is also of potential importance in the analysis of fertility data and which we investigate in our companion paper.

Variations in the sample selection rules used can affect the inference from estimates, such as those presented above, in a nontrivial way. All of the studies cited above are for marital fertility. None correct for the sample selection bias that arises from using such behaviorally conditioned samples. Correc-

tions for selection have been shown to be empirically important in many studies (see Mark Killingsworth, 1983; James Smith, 1980). The appropriate generalization of methods for dealing with selection bias in a dynamic setting is a multistate duration model. In our companion paper, we introduce transitions among birth and nonbirth states using a general multistate process. Specifically, we permit transitions from the single or cohabiting state to the states of marriage and cohabitation, transitions among all three of these states and transitions to births from all possible marital states. We examine the impact of correct conditioning on estimated marital fertility hazard rates, utilizing a multistate specification. Explicitly accounting for the transitions among these life cycle states in estimation of the parameters of the fertility processes corrects for the selection on marital status.

## PERSPECTIVE ON THE EXTERNAL DEBT SITUATION<sup>†</sup>

### International Debt: From Crisis to Recovery?

By WILLIAM R. CLINE\*

Since Mexico temporarily suspended payment in August 1982, the debt crisis has threatened the international financial system and crippled growth in developing countries. Emerging evidence and projection analysis suggest that the problem can be managed, however, if satisfactory growth in the industrial countries can be maintained.

#### I. Origins, Systemic Risk, and Emergency Response

From 1973 to 1982, external debt of non-oil developing countries rose by \$500 billion. Of this amount approximately \$260 billion may be attributed to the exceptional rise in oil prices. Global recession in 1981–82 added another \$100 billion through declines in the terms of trade and reduced export volume; and the excess of real interest rates in this period over historic averages cost them another \$40 billion. External shocks thus accounted for a major portion of the debt crisis. Domestic factors also contributed, especially overvalued exchange rates and inadequate domestic interest rates that caused capital flight (Mexico, Venezuela, and Argentina).

Because debt tends to grow at the interest rate (by "inheritance" from past debt, unless the country runs a trade surplus to pay interest), exports need to grow at least this fast or else the burden of debt relative to exports increases. From 1973 to 1980, international interest rates (including a typical spread above LIBOR) averaged 10 percent, while

nominal export growth from non-oil LDCs averaged 21 percent. But in 1981–82, the interest rate rose to 16 percent while export growth averaged 1 percent. The debt problem may usefully be viewed as the consequence of the shift from low or negative real interest rates in the inflationary 1970's to the high real interest rates of the early 1980's, aggravated by declining real exports during the global recession.

In mid-1982, the nine largest U.S. banks had loans outstanding to developing countries and Eastern Europe amounting to 280 percent of their capital, and most had over 100 percent of capital in loans to just Brazil and Mexico. Large losses on LDC debt could cause technical insolvency in these banks. Attempts to bail out the banks could prove inflationary, while sharp cutbacks in bank capital would mean contractionary pressure as they cut back lending to maintain capital-asset ratios. Although some monetarists have argued that even the large banks could fail without adversely affecting the system if the Fed would maintain steady growth in the money supply, this approach would amount to a global roll of the dice.

Not being gamblers, policymakers responded to the debt crisis with emergency financial packages composed of: 1) a country adjustment program under IMF auspices; 2) continued new lending by banks; and 3) financial support from the IMF, central banks, and multilateral lending institutions.

#### II. Modeling Debt Viability

The premise underlying this policy response was that the debt crisis was one of illiquidity, requiring temporary financing, rather than one of insolvency, involving outright loss of a considerable portion of principal. To examine this question, in the spring of 1983, I developed a projection model for

<sup>†</sup>*Discussants:* Jeffrey Frankel, University of California-Berkeley; Basil G. Kavalsky, World Bank; Henry Wallich, Board of Governors of the Federal Reserve System.

\*Institute for International Economics, 11 Dupont Circle, N.W., Washington, D.C. 20036. References not otherwise specified may be found in my 1984 book.

balance of payments and debt of the 19 largest debtor countries (see my 1983 study).

The model relates exports of the debtor country to OECD growth and the country's real exchange rate. On the basis of a statistical relationship between OECD growth and aggregate non-oil imports, export volume from developing countries is estimated to decline by 3 percent when OECD growth is zero and to increase above this rate by 3 percentage points for each percentage point of OECD growth. The marginal elasticity of exports is 3, and the average elasticity at a typical OECD growth rate of 3 percent is 2. Export prices rise beyond general inflation when OECD growth increases (terms of trade are procyclical), based on relationships estimated for individual countries with data for the past two decades. On average, a 1 percent rise in OECD growth causes approximately 1.5 percent rise in real export price in the current year and a similar rise in the following year. An elasticity of 0.5 is used for the response of exports to the country's real exchange rate.

The model applies a unitary elasticity of real imports with respect to the country's domestic growth, plus an elasticity of three for changes in that growth rate (cyclical elasticity). The elasticity of imports with respect to real exchange rate is  $-0.6$ . Interest payments depend on the previous year's debt as applied to the current year's international interest rate (LIBOR) and a spread. Oil trade is fixed in volume, with values depending on assumed oil prices.

All traded goods (except oil) rise in price, additionally, at the international inflation rate. Also, if the dollar depreciates internationally, dollar prices of traded goods rise (otherwise these goods would command fewer resources internationally because of a change in the dollar-yen or dollar-mark rate) by 80 percent of the depreciation on the basis of trade prices in recent years. Dollar depreciation boosts the dollar value of non-oil exports relative to debt, which is mainly denominated in dollars.<sup>1</sup>

Using this model, my estimates in mid-1983 indicated that the debt problem was indeed one of illiquidity rather than insolvency. Under central expectations for international economic variables (and politically acceptable growth rates in debtor countries), the projections showed that most major countries would show substantial improvement in balance of payments and relative debt burden, and that by the late 1980's, debt-export ratios would be back to levels previously associated with creditworthiness. A return to higher OECD growth would increase export volume and prices, an eventual easing of interest rates would moderate interest payments, and a decline in the dollar from its seriously overvalued level would raise the dollar value of the export base. However, the analysis also indicated that a critical threshold of  $2\frac{1}{2}$  to 3 percent was required for OECD growth to avoid stagnation or severe deterioration in external deficits and debt-export ratios for debtor countries.

Even with gradual recovery from the debt crisis, however, there remains a difficult interim period during which major debtors will not yet have restored creditworthiness to levels necessary for normal capital market access. Where will financial flows come from in this period? Here I have suggested a model of "involuntary lending." In this model, although a country's creditworthiness is too weak for new creditors to risk lending, existing lenders with current exposure will be prepared to make modest new loans to shore up the quality of existing loans. Existing lenders will extend new credit as long as the expected benefit, the reduction in probability of default multiplied by the amount of outstanding exposure, exceeds the expected cost of new lending, the terminal default probability multiplied by the amount of the new loan.

---

would worsen because of the decline in U.S. imports from debtor countries. However, if the country pegs its exchange rate with weights proportionate to partner trade shares, and if trade elasticities are symmetrical, a decline in the dollar will cause increased exports to Europe and Japan that offset any decrease in exports to the United States. Only oil exporters, with oil prices insensitive to the dollar, are likely to be adversely affected by dollar depreciation.

<sup>1</sup>Some appear to believe that if the dollar were to depreciate from its current high level, the debt problem

This model predicts a relatively robust process of continued lending at modest rates. However, it is subject to breakdown because of the free-rider problem. Smaller banks are likely to judge their own actions to have little effect on default probability—even though in the aggregate their actions will affect the outcome.

In a historic departure, the IMF set as a precondition for its own lending that the banks as a group provide significant new lending. Central banks also apparently twisted some arms to ensure participation by smaller banks. These actions helped ensure burden sharing of the public good of increased lending. However, considering that up to two-thirds of bank exposure is held by perhaps 50 to 100 banks internationally, it is likely that a critical mass of banks would have found it in their own interest to provide additional lending even with less official intervention.

So far the mechanism of involuntary lending has held up relatively well. From June 1982 to June 1984, the exposure of U.S. banks in 6 major Latin American debtor countries rose by 9 percent, despite significant reductions in exposure in Argentina and Venezuela by banks other than the largest 24 (Federal Financial Institutions Examination Council, 1984). This rate is approximately equal to the 5 percent annual rate frequently cited as necessary to bridge the period of involuntary lending. Globally, 5 percent growth in exposure corresponds to approximately \$20 billion annually in new bank lending (down from \$50 billion in 1981).

For their part, debtor countries have cooperated and carefully avoided an aggressive debtors' cartel. Even though their interest payments exceed new borrowing, they have little incentive to default, because of immediate adverse consequences (drying up of trade credit, possible seizure of export shipments) and long-term damage to their credit reputation.

### III. Recent Evidence

The emerging evidence in 1983-84 has tended to confirm the analysis that the debt problem is one of illiquidity and subject to

improvement as international recovery takes place. In 1983, the 19 largest debtor countries (accounting for three-fourths of bank debt) cut their external current account deficits from \$56 billion to \$23 billion (an even sharper improvement than in my original projections). Mexico achieved a surplus of \$5.5 billion instead of the deficit of \$3 billion planned under its IMF program. On the strength of a large trade surplus, Brazil will have reduced its current account deficit from \$14 billion in 1982 to less than \$2 billion in 1984. And although cutbacks of imports have played an important role in these turn-arounds, rising exports have also been important. For 8 major Latin American debtors, after declining by 8 percent from 1981 to 1983, export earnings rose by 12 percent in 1984. (Brazil's exports rose by 21 percent, and Mexico's non-oil exports by 35 percent; Morgan Guaranty, 1984.)

The centerpiece of debt recovery has materialized: recovery in the international economy. OECD growth has risen from  $-0.3$  in 1982 to 2.3 percent in 1983, and nearly 5 percent in 1984. There have been adverse developments as well: interest rates rose by 2 percentage points in early 1984 (before moderating), and the dollar has continued to climb instead of depreciating. Nonetheless, the benefits from higher OECD growth have swamped these negative factors. Because 1 percent extra OECD growth offsets 3 percent additional interest charges for non-oil developing countries (in the first year, and more if sustained over several years—although the relationship is less favorable for more highly indebted countries), higher growth in 1984 would have more than compensated for even a sustained 2 percent rise in LIBOR for the year. The most serious setback has been in debtor country growth: Latin American income declined 3 percent in 1983 and per-capita income is 10 percent below the 1980 level. However, growth has once again begun in the region in 1984, with rates of 2 to 3 percent in the major debtor countries, and the prospects are for higher domestic growth in the future.

Projections using updated information through mid-1984 reconfirm the broad analysis that the debt problem is manageable (see

my 1984 book, ch. 8). Even assuming some slowdown in OECD growth (2.7 percent in 1985, 2.3 percent in 1986, and 3 percent in 1987), relatively high interest rates (LIBOR at 12.5 percent in 1984, declining to 9.5 percent only by 1987); and assuming a 20 percent decline of the dollar phased over 1985–86 and oil at \$29 per barrel, the ratio of net debt to exports of goods and services declines from 200 percent in 1983 to 140 percent by 1987 for the 19 largest debtor countries. For Mexico the decline is from 310 percent to 210 percent; for Brazil, from 370 percent to 230 percent; and for Argentina, from a high 490 percent to 320 percent. Moreover, these projections provide for debtor-country growth at politically acceptable rates of  $4\frac{1}{2}$  percent or more per year. And the projections indicate expansion of nominal export earnings at a faster average rate (14.2 percent, 1984–87) than the level of the interest rate (about 12.5 percent including spread), meeting this important test (even though, with trade surpluses, export growth could be lower without increasing the debt-export ratio).

At the end of 1984, it appears that the debtor countries whose debt has systemic consequences are on track for recovery from the debt crisis.<sup>2</sup> External performance has been extremely strong for Brazil and Mexico. Argentina, a source of great concern earlier in the year, has reached agreement with the IMF. Mexico and Venezuela have obtained multiyear rescheduling from the banks; Brazil is likely to do so soon; and Argentina has reached tentative agreement with the banks for a shorter period. Nonetheless, for a secondary tier of some smaller countries, external sector pressures are more serious, in part because their exports are concentrated in commodities with weak prices. Chile and Peru face severe difficulties, although these should moderate once dollar depreciation and/or interest rate reductions permit more

normal recovery of metals prices. Bolivia, Nicaragua, Poland, Sudan, and Zaire—all on the bank regulators' list of "value impaired"—appear to have more protracted problems. Their aggregate debt is too small to threaten the system, however, and in some cases the best option may simply be to allow their arrears to accumulate.

Other studies have also reached the conclusion that broad recovery from the debt crisis may be expected (Morgan Guaranty; International Monetary Fund, 1984; Ronald Leven and David Roberts, 1983). Some critics have challenged the responsiveness of debtor country exports to OECD growth (Rudiger Dornbusch, 1984), but most studies tend to confirm an average volume elasticity in the range of 2 (the value in my model) and sufficient terms of trade response to boost the (average) revenue elasticity to approximately 3 (see the studies just cited and Carlos Diaz-Alejandro, 1984).<sup>3</sup>

Some critics have challenged such projections on grounds that the chances are small that the international economic variables will turn out exactly as assumed. However, this criticism loses force if one considers that if departures from projected values of exogenous variables are randomly distributed, favorable departures in some (such as OECD growth in 1984) will offset adverse departures for others (such as interest rates and dollar strength in 1984).

Some important conceptual underpinnings of this outlook require clarification. First, it assumes interest payments will exceed new borrowing (there will be an "outward transfer of resources"). While some question the political viability of this assumption, this outcome is prudent and necessary to reduce debt-export ratios from levels associated with overborrowing in the past. Moreover, with

<sup>2</sup> Brazil (\$92 billion total debt); Mexico (\$88 billion); Argentina (\$44 billion); and Venezuela (\$34 billion) account for three-fourths of bank debt owed by countries with debt-servicing disruptions in 1982–84 (see my 1984 study, pp. 25; 165).

<sup>3</sup> Thomas Enders and Richard Mattione (1984) project improvement on debt, but predict, somewhat questionably, painfully low Latin American domestic growth. The Inter-American Development Bank (1984) projects massive deficits even if Latin American growth is merely sufficient to keep up with population; but the study's parameters and assumptions stand in doubt (see my 1984 study, pp. 172–74).

domestic growth led by the export sector, an interim period of outward resource transfer need not mean slow domestic growth.

Second, the projections involve lower real import-GDP ratios than in the early 1980's for some major countries. Argentina, Mexico, and Venezuela had bloated import levels now corrected by real depreciation, and even allowing for significant rebounds, imports should not return to earlier levels. Brazil's sharp increase in production of oil and other import substitutes has accomplished the same objective. Adjustment is shifting to the expenditure-switching phase (shift in resource allocation from nontradables to exports and import substitutes), so that domestic growth can be higher than in the earlier expenditure-reducing (recessionary) phase.

Third, a caveat is that domestic inflation may have already become a more binding constraint on growth than external debt. Brazil's inflation exceeds 200 percent and Argentina's 700, and monetary-fiscal restraint to reduce inflation may hold back near-term growth, while politically debt may be blamed.

#### IV. Policy Implications

Despite favorable emerging economic reality, the debt problem remains politically vulnerable. The lagged effects of severe recession in 1983, and the runup in interest rates early in 1984, have caused political pressure, as shown by the emergence of the Cartagena group of Latin American debtor countries. The best strategy for the international financial system would be to pursue additional measures, to consolidate the gains made to date and insure against political disruption from possible future setbacks.

Macroeconomic policy in the North must ensure continued recovery. The U.S. fiscal deficits should be cut to permit more relaxed monetary policy, lower interest rates, and a lower dollar; and Europe and Japan should avoid further fiscal tightening until recovery is consolidated. A critical threshold of approximately  $2\frac{1}{2}$  percent for OECD growth is still the key to managing international debt (although the strong performance of 1984 leaves room for modest deceleration).

Sweeping measures on debt should be avoided. Write-downs and consolidation of debt in a new international agency would not only require scarce public capital and injure the debtors' credit ratings, but would also choke off the incentive for involuntary bank lending, as banks no longer would hold claims on the country. Interest forgiveness (such as a cut of all interest rates in half) would do great damage to the (highly leveraged) banks without providing much growth benefit for debtor countries (especially after deducting the loss of new lending).

For their part, banks need to continue aggregate new lending to developing countries at perhaps \$20 billion annually. They should extend "Mexico-type" (September, 1984) packages of reduced spreads above LIBOR and multiyear reschedulings, especially to countries that demonstrate effective adjustment. In addition, the banks would do well to provide some insurance against interest rate surges by offering a "Reimbursable Interest-Averaging Cap," whereby interest above a given ceiling (set near the initial market rate) would be deferred if international interest rates rose, and repaid once rates declined again. Banks could charge some spread premium for this benefit, and even obtain private insurance of amounts deferred.

The International Monetary Fund could usefully introduce a Compensatory Finance Facility for interest rate surges, to complement its facility for export fluctuation. Expanded resources are necessary for lending by the World Bank, regional development banks, and export credit agencies, so that the official sector can help redress the excessive shift from official to private financial sources in the past several years. Finally, industrial countries must avoid increased protection against imports from developing countries.

In sum, the major debtor countries have made much progress in recovering from the debt crisis. International management of the crisis on a case-by-case basis has amounted to a coherent strategy that has in fact shown favorable results so far. Nonetheless, considerable risk remains. The most serious, but not necessarily most likely, risk is from a collapse in OECD growth, the motor force in

debt recovery. The sharp slowdown in U.S. economy in late 1984 is troubling. Nonetheless, the likely absence of further oil shocks in the 1980's, and the fact that growth now begins from a base of much-reduced inflation, suggest that international growth rates closer to those achieved in the 1950's and 1960's than those of 1974-82 should be attainable. Overall, a series of moderate measures along the lines suggested here should be sufficient to consolidate the political and economic basis for continued recovery from the debt crisis, making it possible for international lending to return to a much more normal basis by the late 1980's.

# Latin American Debt: Lessons and Pending Issues

By EDUARDO WIESNER\*

Two years have gone by since the international debt crisis surfaced in late 1982. Although this brief period may not provide enough perspective to draw firm conclusions, it would seem sufficient for arriving at some understanding of the causes and consequences of the crisis. In this paper I shall try to identify some of the lessons that can be derived from this experience. I will also look into the direction in which the current situation is evolving to see what are some of the main emerging issues. Needless to say, the paper does not pretend to be exhaustive or conclusive. Its principal purpose is to contribute to that continuing exercise whereby theory is tested by its predictive capabilities. The particular experience of the debt crisis seems to offer fertile ground to engage in this exercise because, as Jeffrey Sachs has stated, "it points up a lesson relearned several times in the past one hundred and fifty years: the international loan markets function differently from the textbook model of competitive lending" (1984, p. 1).

The paper is organized as follows. After succinctly reviewing the factors behind the debt crisis, I submit that the traditional absorption approach should be complemented to take into account the difficulties of developing countries in absorbing external savings efficiently. Then, I discuss the role of risk in the debt problem. It is in these two particular areas where I believe some of the most significant lessons can be extracted. Finally, I comment briefly on some of the issues that currently confront policymakers in Latin American countries.

## I. The Fiscal Origin of the Debt Crisis

No other set of factors explains more of the debt crisis than the fiscal deficits incurred by most of the major countries in Latin America. Although there were other factors which were relevant, I have no doubt that the main problem was excessive public (and private) spending that was financed by both easy domestic credit policies and by ample resources from abroad. The world recession and high real rates of interest in international markets aggravated the crisis, but I do not believe they created it. What actually happened was that previous domestic macroeconomic policies had made economies more vulnerable to exogenous factors.

The figures for the period 1979-82 cannot be more eloquent. In only four years, the three largest countries of the region—Argentina, Brazil, and Mexico—more than doubled the size of their nonfinancial public sector deficits, which rose from the already high levels of around 6 percent of *GDP* to well over 15 percent. Behind these growing fiscal deficits were strong political pressures for higher public spending. As long as external financing permitted total absorption to exceed domestic income, it was possible to accommodate those demands. But as the world recession worsened, and as it became evident that the additional financing from abroad was not being accompanied by a corresponding increase in exports or in domestic capital formation, capital inflows dropped substantially and the fiscal imbalance became an exchange rate and debt crisis. In brief, the debt crisis can be traced back to a fiscal disequilibrium, and ultimately to an unresolved political struggle between competing groups that wanted to have a larger share of income.

This view of the debt crisis as a fiscal manifestation of a political struggle may explain why it is still so difficult to resolve some of the most severe problems of the

\*Director, Western Hemisphere Department, Room 10-100, International Monetary Fund, Washington, D.C. 20431. The opinions expressed here are my own and do not necessarily reflect the views of the International Monetary Fund.

adjustment process. The intractability would arise because at the bottom of the adjustment process there still lies partially unsettled the question of who is going to pay for that portion of absorption which was not covered by taxes, has not become a productive investment within the debtor country, was presumably and to some extent a creditor risk, and may be by now gone forever. Under peremptory, abrupt adjustment, these political questions are resolved without delay by force of circumstances. But under managed adjustment, which is clearly preferable, the attempt to control the process may also allow, in some cases, for postponement of at least part of the most difficult political decisions, and thus it runs the risk of prolonging uncertainty and making recovery more elusive. This is a delicate political issue. Its importance lies in that it may explain why sometimes the gradual approach to adjustment does not seem to work.

## II. The Absorption of Foreign Financing

The combined external debt of Argentina, Brazil, Chile, Mexico, Peru, and Venezuela more than doubled between 1978 and 1982. This huge inflow of external resources was, of course, largely the other face of the large fiscal and current account deficits. External financing was allowing these countries to sustain absorption levels higher than national income. That is, domestic consumption and investment exceeded national income. Since most of the external financing came from private international banks, it was widely believed then that these countries were creditworthy and were effectively utilizing external savings. In some instances, the external financing was even allowing (if not inducing) real appreciation of the exchange rate and was luring policymakers into believing that a new era of low inflation, high growth, and exchange rate stability was about to begin. B. Kavalsky and L. Squire et al. (1984) point out that in countries like Peru, Argentina, and Mexico, real exchange rates actually appreciated. We now know that little of this proved to be a reality. Unfortunately, debt accumulation was not, according to Rudiger Dornbusch and Stanley

TABLE 1—SAVINGS AND INVESTMENT  
(As percent of *GDP*)

	1980	1981	1982	1983
<b>Argentina</b>				
Gross domestic investment	25.7	20.0	18.1	17.1
National savings	22.6	16.2	13.0	13.3
External savings	3.1	3.8	5.0	3.8
<b>Brazil</b>				
Gross domestic investment	21.1	19.2	18.4	15.0
National savings	16.0	15.1	12.9	12.0
External savings	5.1	4.1	5.5	3.0
<b>Mexico</b>				
Gross domestic investment	28.1	29.0	21.2	16.5
National savings	24.0	23.2	17.8	20.2
External savings	4.1	5.8	3.4	-3.7

Fischer, "financing investment that was productive by the test of net dollar earnings" (1984, p. 4). After the initial appreciation of local currencies capital inflows turned into capital outflows (Arnold Harberger, 1984) precipitating sharp depreciations of the real exchange rate.

While the flows of external financing were pouring into the countries, two fundamental developments were taking place. The first, domestic savings as a proportion of *GDP*, was not increasing and, in most cases, was actually declining. Furthermore, gross domestic investment actually declined as a percentage of *GDP*. Countries were absorbing external resources (Ricardo Ffrench-Davis, 1983), but they were not using all of them to increase investment but rather to allow for more consumption. Since the accumulation of external debt was growing at a faster pace than the accumulation of productive investment,<sup>1</sup> a debt crisis was just a question of time, which would prove shorter in the event of external monetary disturbances. (See Table 1.)

The second very important development that was taking place had to do with the weakening, (B. A. de Vries, 1983) of the link

<sup>1</sup>H. J. Kharas holds that "the critical relationship in debt analysis is that between the accumulation of productive capital relative to external debt" (1984, p. 419).

between external financing and specific project investment evaluation. Since most of the additional external financing came from international commercial banks, and since the debtors generally were public sectors, the importance of the economic feasibility of investment projects was diluted. This meant that the global quality of the investment programs deteriorated and that many projects were initiated not because they were economically sound but because they had found external commercial financing which, directly or indirectly, was guaranteed by a sovereign debtor. And as Alexander Swoboda has pointed out, banks are "willing to acquire assets at rates of return lower than the riskiness of these assets" (1985, p. 24), if there is a guarantee. This development contrasted sharply with the traditional external financing for specific investment projects provided by multilateral agencies like the World Bank or the Inter-American Development Bank.

The lessons from this are not novel in my view, and yet recent experience would suggest that they need to be emphasized. To begin with, developing countries do not have an unlimited capacity to absorb external resources, because their absorptive investment capacity sets a limit to the volume of resources that they can utilize efficiently.<sup>2</sup> There are limits to the taxing capacity of developing countries' public sectors. Higher fiscal deficits may end up being financed by external savings, but this does not necessarily mean that all of these savings (Donough McDonald, 1982) become investments in the debtor countries or that the margin created by those additional external resources is used to increase investment.

### III. The Role of Risk Revisited

Although the debt crisis can be explained mainly in terms of fiscal deficits and inadequate economic policies in the debtor countries, it could also be explained by the wrong

perceptions that debtors and creditors had about the real risks they were taking. Had they had perfect foresight about these risks, no major crisis could have developed. A serious crisis can only result from a cumulative process. In the case of the current debt crisis, fiscal deficits and external debt accumulated because the risk factor did not play *ex ante*, in the early stages, its crisis-defusing role.

The experience of this debt crisis teaches that at least two of the fundamental risk assumptions that guided international lending and borrowing were wrong. First, international banks assumed that a sovereign risk was a small risk because public sectors normally do not default. As a result, they did not pay sufficient attention to the quality of economic policies in the debtor countries nor did they worry about the economic feasibility of the investment projects they were, directly or indirectly, financing. Apparently, they thought that an, implicit or explicit, official guarantee was all that was needed to circumvent risk. Perhaps it was considered that high spreads—internal and external—were sufficient to cover for any possible extra risk incurred. Finally, it is not clear what the risk perception of international banks was with regard to their lending to private banks or enterprises in the debtor countries.

Second, governments understood that if private flows were freely coming in to finance their expenditures, then their macroeconomic policies could not be all that bad and their exchange rates could not be much out of line with long-term equilibrium rates. In fact, they often found it difficult to control expenditure and to follow more prudent macroeconomic policies simply because the external financing was there. On the other hand, public sectors thought they were not taking any risks in the case of private external lending to their private sectors. Thus, they did not establish adequate controls or precise conditionality for that modality of international financing. The model<sup>3</sup> of international

<sup>2</sup>Sidney Alexander in his celebrated article did not imply that investment necessarily increased when external financing was available. His assertion was that both investment and consumption taken together could be higher than national income (1952, p. 265).

<sup>3</sup>See A. W. Corden for an interesting discussion on the distinction "between private problems and public problems" in the area of balance of payments (1977, p. 45).

lending held that these transactions could not pose a risk to public sectors, since, as Tim Congdon has put it, "there is no such thing as a balance of payments problem between consenting adults" (1982, p. 5).

We now have relearned that public sectors of borrowing countries can find themselves unable to service their debts and that, in some cases, debtor countries have been unable to resist pressures to guarantee private loans or to provide some form of exchange rate guarantee. This has converted a private risk into a fiscal burden. When I say that now we know the obvious, I am, of course, speaking within the context of what I have called above the investment absorption capacity of less developed countries. Nothing very original. It used to be almost an axiom a few years ago when few, if anyone, thought that developing countries could absorb massive doses of financial resources. They did not have an infinite amount of economically feasible investment projects, nor could they hope to have instant improvement in the quality of their macroeconomic policies. These realities, that meant risks, were temporarily forgotten.

Risk is a stabilizing factor in the functioning of markets. The insurance or guarantee of loans against risk may actually increase willingness to incur risk.<sup>4</sup> This is the so-called moral hazard problem. Attempts to interfere with the role of risk is a very risky exercise like the current crisis has confirmed. The process of delinking risk from the economic feasibility of investment projects and from the capacity of debtor countries to rapidly adopt all of the right macroeconomic policies in the face of abundant external financing is one of the most underestimated causes of the debt crisis. In brief, both debtors and creditors made wrong decisions on the basis of wrong perceptions of their respective risks.

One basic question emerges out of the above analysis. If both debtors and creditors share responsibility in the formation of the debt crisis, how are the costs of the resolution of that crisis going to be apportioned?

In principle, strict adherence to the role of risk would mean that the market would distribute the costs of resolving the crisis. In essence, this would mean that creditors would sell their claims in the market—and thus absorb in losses the reduced value of these claims—and divorce themselves from their debtors. For the debtors, the market solution would mean instant adjustment without financing and according to Jonathon Eaton and Mark Gersovitz, "an embargo on future loans" (1981, p. 290).

These hypothetical scenarios surely have been considered by both debtors and creditors since they would be the consequence of not providing any rescheduling or new money, on the one hand, and of defaulting on the other. The answer that both debtors and creditors have decided to give to the debt crisis is to manage jointly the resolution of their conflicting interests. The fact that both parties have chosen or resigned themselves to this route can be interpreted as an *ad hoc* market solution in which they have carefully assessed the risks of all alternatives and have come to the conclusion that their losses are minimized under this alternative.

#### IV. Choices and Issues

At this juncture, critical choices are being made in at least the following two main areas: international borrowing and lending; and the openness and efficiency of the economies of the Latin American countries. The first choice concerns the question of what to do about borrowing. While it is true, as William Cline has said, that "these countries have erred on the side of excessive borrowing in the last decade" (1984, p. 178), the question now is how to reduce the rate and, if possible, the level of indebtedness—which is the desirable thing to do—if at the same time there is a need to mitigate the tribulations of adjustment. This is a formidable dilemma. More financing alleviates adjustment, but simultaneously adds to the debt service. There is no simple solution to this predicament. At the bottom of the circularity involved there lies, once again, the question of how should the costs of the resolution of the crisis be apportioned. Until now, both parties have opted for negotiations rather

<sup>4</sup>See Henry Wallich for an excellent discussion of the risks and advantages of insurance on bank lending (1984).

than confrontation. While it is not possible to predict what will be the final outcome, it could be said that the answer will largely depend on what happens to the world economic recovery and to the export earnings of indebted countries. In the words of Mario Simonsen, "a growing economy with expanding exports hardly would seek confrontation with its creditors" (1984, p. 68).

The second area where difficult choices have to be made concern the degree of openness and of economic efficiency of the region. The issue here is how to preserve long-term efficiency when short-term and urgent pressures make it attractive to reduce openness and to seek economic reactivation through protectionism. The prospects in this area are not encouraging. Unfortunately, it seems that one of the most costly consequences of the debt crisis is that, at the end, some Latin American countries will be more closed and less efficient. At this juncture it seems that some policymakers of the region are striving to avoid a repetition of the crisis of 1982 and 1983. Apparently, they find it preferable to accumulate international reserves than to increase imports and to open up trade; they find it less destabilizing—and more fiscally productive—to raise import tariffs than to promote exports through the exchange rate. And in the future, they may feel less vulnerable if they regulate or control international capital flows than if they open up and let market risk, once again, be the final arbiter. Unfortunately, on the basis of the recent experience, some policymakers are apprehensive about what to expect from the free play of the market forces.

## THE USE AND ABUSE OF ECONOMETRICS<sup>†</sup>

### Data and Econometricians—The Uneasy Alliance

By ZVI GRILICHES\*

Econometricians have an ambivalent attitude towards economic data. At one level, the "data" are the world that we want to explain, the basic facts that economists purport to elucidate. At the other level, they are the source of all our troubles. Their imperfection makes our job difficult and often impossible. Many a question remains unresolved because of "multicollinearity" or other sins of the data. We tend to forget that these imperfections give us our legitimacy in the first place. If the data were perfect, collected from well-designed randomized experiments, there would be hardly room for a separate field of econometrics. Given that it is the "badness" of the data that provides us with our living, perhaps it is not all that surprising that we have shown little interest in improving it, in getting involved in the grubby task of designing and collecting original data sets of our own. Most of our work is on "found" data, data that have been collected by somebody else, often for quite different purposes.

Economic data collection started primarily as a by-product of other governmental activities: tax and customs collections. Early on, interest was expressed in prices and levels of production of major commodities. Besides tax records, population counts, and price surveys, the earliest large-scale data collection efforts were various censuses, family expenditure surveys, and farm cost and production surveys. By the middle 1940's the overall economic data pattern was set:

governments were collecting various quantity and price series on a continuous basis, with the primary purpose of producing aggregate level indicators such as price indexes and national income accounts series, supplemented by periodic surveys of population numbers and production and expenditure patterns to be used primarily in updating the various aggregate series. Little micro data was published or accessible, except in some specific subareas, such as agricultural economics.

A pattern was also set in the way the data were collected and by whom they were analyzed. With a few notable exceptions, such as France and Norway, and until quite recently, econometricians were not to be found inside the various statistical agencies, and especially not in the sections that were responsible for data collection. Thus, there grew up a separation of roles and responsibilities. "They" collect the data and they are responsible for all their imperfections. "We" try to do the best with what we get, to find the grain of relevant information in all the chaff. Because of this, we lead a somewhat remote existence from the underlying facts we are trying to explain. We did not observe them directly; we did not design the measurement instruments; and, often we know little about what is really going on (for example, when we estimate a production function for the cement industry from census data without ever having been inside a cement plant).

In this we differ quite a bit from other sciences (including observational ones rather than experimental) such as archeology, astrophysics, biology, or even psychology where the "facts" tend to be recorded by the professionals themselves, or by others who have been trained and are supervised by those who will be doing the final data analysis.

<sup>†</sup>*Discussants:* Dale W. Jorgenson, Harvard University; A. H. Studenmund, Occidental College.

\*Professor of Economics, Harvard University, 125 Littauer Center, Cambridge, MA 02138. This paper is adapted from my larger manuscript (1985) which can be seen for more detail, examples, and references.

Economic data tend to be collected (or often more correctly "reported") by firms and persons who are not professional observers and who do not have any stake in the correctness and precision of the observations they report. While economists have increased their use of surveys in recent years and have even begun designing and commissioning special purpose surveys of their own, in general, the data collection and thus the responsibility for the quality of the collected material is still largely delegated to census bureaus, survey research centers, and similar institutions, and is divorced from the direct supervision and responsibility of the analyzing team.

It is only relatively recently, with the initiation of the negative income tax experiments and various longitudinal surveys intended to follow up the effects of different governmental programs, that econometric professionals have actually become involved in the primary data collection process. Once attempted, the job turned out to be much more difficult than was thought originally, and taught us some humility. Even with relatively large budgets, it was not easy to figure out how to ask the right question and to collect relevant answers. In part this is because the world is much more complicated than even some of our more elaborate models allowed for, and partly because economists tend to formulate their theories in non-testable terms, using variables for which it is very hard to find empirical counterparts. For example, even with a large budget, it is difficult to think of the right series of questions, answers to which would yield an unequivocal number for *the* level of "human capital" or "permanent income" of an individual. Thinking about such "alibi-removing" questions should make us a bit more humble, restrain our continuing attacks on the various official data-producing agencies, and push us towards formulating theories with more regard to what is observable and what kind of data may be available.

Even allowing for such reservations, there has been much progress over the years as a result of the enormous increase in the quantity of data available, in our ability to manipulate them, and in our understanding

of their limitations. Especially noteworthy have been the development of various longitudinal micro data sets (such as the Michigan PSID tapes, the Ohio State *NLS* surveys, the Wisconsin high school class follow-up study, and others), the computerization of the more standard data bases and their more easy accessibility at the micro, individual response level (I have in mind here such developments as the Public Use Samples from the *U.S. Census of Population* and the *Current Population Surveys*). Unfortunately, much more progress has been made with labor force and income data, where the samples are large, than in the availability of firm and other market transaction data.

While significant progress has been made in the collection of financial data and security prices, as exemplified in the development of the CRISP and Compustat data bases which have had a tremendous impact on the field of finance, we are still in our infancy as far as our ability to interrogate and get reasonable answers about other aspects of firm behavior. Most of the available micro data at the firm level are based on legally required responses to questions from various regulatory agencies who do not have our interests exactly in mind.

We do have now, however, a number of extensive longitudinal micro data sets that have opened a host of new possibilities for analysis and also raised a whole range of new issues and concerns. After a decade or more of studies that try to use such data, the results have been somewhat disappointing. We, as econometricians, have learned a great deal from these efforts and developed whole new subfields of expertise, such as sample selection bias and panel data analysis. We know much more about these kinds of data and their limitations, but it is not clear that we know much more about the roots and modes of economic behavior that underlie them.

The encounters between econometricians and data are frustrating and ultimately unsatisfactory, both because econometricians want too much from the data and hence tend to be disappointed by the answers, and because the data are incomplete and imperfect. In part it is our fault, the appetite grows with

eating. As we get larger samples, we keep adding variables and expanding our models, until on the margin, we come back to the same insignificance levels.

There are at least three interrelated and overlapping causes of our difficulties: 1) the theory (model) is incomplete or incorrect; 2) the units are wrong, either at too high a level of aggregation or with no way of allowing for the heterogeneity of responses; and 3) the data are inaccurate on their own terms, incorrect relative to what they purport to measure. The average applied study has to struggle with all three possibilities.

At the macro level and even in the usual industry level study, it is common to assume away the underlying heterogeneity of the individual actors and analyze the data within the framework of the "representative" firm or "average" individual, ignoring the aggregation difficulties associated with such concepts. In analyzing micro data, it is much more difficult to evade this issue and hence much attention is paid to various individual "effects" and "heterogeneity" issues. This is where longitudinal data can be of help—in their ability to control and allow for additive individual effects. On the other hand, as is the case in most other aspects of economics, there is no such thing as a free lunch: going down to the individual level exacerbates both some of the left-out variables problems and the importance of errors in measurement. Variables such as age, land quality, or the occupational structure of an enterprise, are much less variable in the aggregate. Ignoring them at the micro level can be quite costly, however. Similarly, measurement errors which tend to cancel out when averaged over thousands or even millions of respondents, loom much larger when the individual is the unit of analysis.

It is possible, of course, to take an alternative view: that there are no data problems, only model problems in econometrics. For any set of data there is the "right" model. Much of econometrics is devoted to procedures which try to assess whether a particular model is right in this sense and to criteria for deciding when a particular model fits and is "correct enough." Theorists and model builders often proceed, however, on the as-

sumption that ideal data will be available and define variables that are unlikely to be observable, at least not in their pure form. Nor do they specify in adequate detail the connection between the actual numbers and their theoretical counterparts. Hence, when a contradiction arises, it is then possible to argue "so much worse for the facts."

In practice one cannot expect theories to be specified to the last detail nor the data to be perfect or of the same quality in different contexts. Thus any serious data analysis has to consider at least two data generation components: the economic behavior model describing the stimulus-response behavior of the economic actors and the measurement model describing how and when this behavior was recorded and summarized. While it is usual to focus our attention on the former, a complete analysis must consider them both. (At this point in the longer manuscript, there follows a review of types of economic data, notions of data "quality," and a discussion of the major problems associated with the use of different sources and types of data.)

Over thirty years ago, Oscar Morgenstern (1950) asked whether economic data were accurate enough for the purposes that economists and econometricians were using them for. He raised serious doubts about the quality of many economic series and implicitly about the basis for the whole econometrics enterprise. Years have passed and there has been very little coherent response to his criticisms.

There are basically four responses to his criticism and each has some merit. 1) The data are not that bad. 2) The data are lousy but it does not matter. 3) The data are bad but we have learned how to live with them and adjust for their foibles. 4) That is all there is—it is the only game in town and we have to make the best of it.

There clearly has been great progress both in the quality and quantity of the available economic data. In the United States, much of the agricultural statistical data collection has shifted from judgment surveys to probability-based survey sampling. The commodity coverage in the various official price indexes has been greatly expanded and much more attention is being paid to quality change

and other comparability issues. Decades of criticisms and scrutiny of official statistics have borne some fruit. Also, some of the aggregate statistics have now much more extensive micro data underpinnings. It is now routine in the United States to collect large periodic labor force activity and related topics surveys and release the basic micro data for detailed analysis with relative short lags. But both the improvements in and the expansion of our data bases have not really disposed of the questions raised by Morgenstern. As new data appear and as new data collection methods are developed, the question of accuracy persists. While quality of some of the "central" data has improved, it is easy to replicate some of Morgenstern's horror stories even today. For example, in 1982 the U.S. trade deficit with Canada was either \$12.8 or \$7.9 billion depending on whether this number came from U.S. or Canadian publications. It is also clear that the national income statistics for some of the LDCs are more political than economic documents.

Morgenstern did not distinguish adequately between levels and rates of change. Many large discrepancies represent definitional differences, and studies that are mostly interested in the movements in such series may be able to evade much of this problem. The tradition in econometrics of allowing for "constants" in most relationships and not overinterpreting them, allows implicitly for permanent "errors" in the levels of the various series. It is also the case that in much of economic analysis, one is after relatively crude first-order effects and these may be rather insensitive even to significant inaccuracies in the data. While this may be an adequate response with respect to much of the standard, especially macroeconomic analysis, it seems inadequate when we contemplate some of the more recent elaborate nonlinear multi-equational models being estimated at the frontier of the subject. They are much more likely to be sensitive to errors and inconsistencies in the data.

In the recent decade there has been a revival of interest in "error" models in econometrics, though the progress in sociology on this topic seems more impressive.

Recent studies using micro data from labor force surveys, negative-tax experiments, and similar data sources exhibit much more sensitivity to measurement error and sample selectivity problems. Even in the macro area there has been some progress, and the "rational expectations" wave has made researchers more aware of the discrepancy between observed data and the underlying forces that are presumably affecting behavior. All of this has yet to make a major dent on econometric textbooks and econometric teaching, but there are signs that change is coming. It is more visible in the areas of discrete variable analysis and sample selectivity issues than in the errors of measurement area per se, but the increased attention that is devoted to data provenance in these contexts is likely to spill over into a more general data "aware" attitude.

One of the reasons why Morgenstern's accusations were brushed off was that they came from "outside" and did not seem sensitive to the real difficulties of data collection and data generation. In most contexts the data are imperfect not by design, but because that is all there is. Empirical economists have over generations adopted the attitude that having bad data is better than having no data at all, that their task is to learn as much as is possible about how the world works from the unquestionably lousy data at hand. While it is useful to alert users to their various imperfections and pitfalls, the available economic statistics are our main window on economic behavior. In spite of the scratches and the persistent fogging, we cannot stop peering through it and trying to understand what is happening to us and to our environment, nor should we. The problematic quality of economic data presents a continuing challenge to econometricians. It should not cause us to despair, but we should not forget it either.

The availability of longitudinal micro data has helped by providing us with one way of controlling for missing but relatively constant information on individuals and firms. It is difficult, however, to shake off the impression that, here also, the progress of econometric theory and computing ability is outracing the increased availability of data

and our understanding and ability to model economic behavior in increasing detail. While we tend to look at the newly available data as adding degrees of freedom grist to our computer mills, the increased detail often raises more questions than it answers. Particularly striking is the great variety of responses and differences in behavior across firms and individuals. Specifying additional distributions of unseen parameters rarely adds substance to the analysis.

What is needed is a better understanding of the behavior of individuals, better theories and more and different variables. Unfortunately, standard economic theory deals with "representative" individuals and "big" questions, and does not provide much help in explaining the production or hiring behavior of a particular plant at a particular time, at least not with the help of the available variables. Given that our theories, while couched in micro language, are not truly micro oriented, perhaps we should not be

asking such questions. Then what are we doing with micro data? We should be using the newly available data sets to help us find out what is actually going on in the economy and in the sectors that we are analyzing, without trying to force our puny models on them. The real challenge is to try to stay open, to learn from the data, but also, at the same time, not drown in the individual detail. We have to keep looking for the forest among all these trees.

# The Loss Function Has Been Mislaid: The Rhetoric of Significance Tests

By DONALD N. MCCLOSKEY\*

Roughly three-quarters of the contributors to the *American Economic Review* misuse the test of significance. They use it to persuade themselves that a variable is important. But the test can only affirm a likelihood of excessive skepticism in the face of errors arising from too small a sample. The test does *not* tell the economist whether a fitted coefficient is large or small in an economically significant sense.

The criticism is distinct from the criticism that in a world of publication-counting deans, there is an incentive to mine the data, giggling uncomfortably when caught. Economists, being professional cynics, are much amused by data mining and significance fishing (Gordon Tullock, 1959; Edward Ames and Stanley Reiter, 1961; Edgar Feige, 1975; Edward Leamer, 1978; Thomas Mayer, 1980; Michael Lovell, 1983; Frank Denton, 1985). But the point here is that even under classical conditions the *t*-test is irrelevant much of the time.

Neither criticism is controversial or arcane. Statisticians, psychometricians, sociometricians, econometricians, and other metrical folk have understood them both for 60 years (see Kenneth Arrow, 1960; Zvi Griliches, 1976). Both should be parts of the statistical education of an economist, yet almost none of the texts in econometrics mention them.

## I. An Example: Tests of Purchasing Power Parity

The usual test of purchasing power parity (see J. R. Zecher and myself, 1984) fits prices

at home ( $P$ ) to prices abroad ( $P^*$ ), allowing for the exchange rate ( $e$ ):  $P = \alpha + \beta(eP^*) + \text{error term}$ . The equation can be in levels or rates of change. If the coefficient  $b$  is statistically significantly different from 1.0, the hypothesis of purchasing power parity is rejected; if not, not. The test seems to tell about substantive significance without any tiresome inquiry into how true a hypothesis must be in order to be true. The table of  $t$  will tell.

But a number is large or small relative only to some standard. Forty degrees of frost is paralyzing cold by the standard of Virginia, a normal day by the standard of Saskatoon in January, and a heat wave by the standard of most interstellar gas. A *New Yorker* magazine cartoon shows water faucets labeled "Hot (A Relative Concept)" and "Cold (A Relative Concept)." Nothing is large-in-itself. It is large (or yellow, rich, cold, stable, well-integrated, selfish, free, rising, monopolistic) relative to something with which it can be interestingly compared. The remark "But how large is large?" is one of those seminar standbys, applying to any paper, like "Have you considered simultaneity bias?" or "Are there unexploited opportunities for entry?" It's usually a good question, inheriting some of its excellence from its father in thought, the mind-stunning "So What?" (and its Jewish mother: "So What Else is New?"). You say the coefficient is 0.85 with a standard error of 0.07? So?

The literature does not discuss how near the slope has to be to 1.0 to be able to say that purchasing power parity succeeds or fails. It does not answer how large is large. The only standard offered is statistical significance, that is, how surprising it would be to get the observed sample if the hypothesis of  $\beta = 1.0$  were in fact exactly true.

But "exactly" true is not relevant for most economic purposes. What is relevant is merely that  $\beta$  is in the neighborhood of 1.0,

\*Departments of Economics and of History, University of Iowa, Iowa City, IA 52242. I thank Leanne Swenson for research assistance, and seminar participants at Iowa, Nebraska, Yale, Chicago, and McMaster for comments. The work was supported by the John Simon Guggenheim Foundation, the Institute for Advanced Study, and the Program in Humanities, Science and Technology of the National Endowment for the Humanities.

where "the neighborhood" is defined by *why* it is relevant—for policy, for academic reputation, for the progress of knowledge. The question requires thought about the loss function. One begins to think that the neighborhood of small loss might be large. And even outside it, one begins to think that  $\beta = .10$ , say, would still be economically significant, were the fit tight enough to constrain prices at home; or that even a coefficient of  $-7854.86$  would belie closed economy models of inflation.

The usual test does not discuss standards. It gives them up in favor of irrelevant talk about the probability of a type I error in view of the logic of random sampling. Most economists appear to have forgotten how narrow is the question that a statistical test of significance answers. It tells the intrepid investigator how likely it is that, *because of the small size of the sample he has*, he will make a mistake of excessive skepticism in rejecting a true hypothesis (in this case,  $\beta = 1.0$ ). Though not to be scorned, it isn't much. It warns him about a certain narrow kind of foolishness.

The elementary but neglected point is that statistical tests of significance are merely about one sort of unbiased errors in *sampling*. The standard error, after all, is  $(s^2/N)^{1/2}$ . Except in the limiting case of literally zero correlation, if the sample were large enough all the coefficients would be significantly different from everything. The inverse of the square root of an extremely large number is very small. Any social scientist with large samples has had such logic impressed on him by events. A psychologist, Paul Meehl, for instance, reports a sample of 55,000 Minnesota high school seniors which "reveal statistically significant relationships in 91 percent of pairwise associations among a congeries of 45 miscellaneous variables such as sex, birth order, religious preference, . . . , dancing, interest in woodworking. . . . The majority of variables exhibited significant relationships with *all but three of the others*, often at a very high confidence level" (1970, p. 259).

The large-sample case makes clear the irrelevance of statistical significance to the main question: So what? In the usual test of

purchasing power parity, a sample size of a million yielding a very tight estimate that  $\beta = 0.999$ , "significantly" different from 1.0, could be produced under the usual procedures as evidence that the theory had "failed." Common sense, presumably, would rescue the investigator from asserting that if  $\beta = 0.999$ , with a standard error of .00000001, we should abandon purchasing power parity, or run our models of the American economy without the world price level. Similar common sense should be applied to findings that  $\beta = .80$  or 1.30 with sample sizes of 30. It is not.

The point can be put most sharply by supposing that we *knew* the coefficient to be, say, 0.85. Suppose God told us. God does not play dice with the universe, and His is no mere probabilistic assurance. Would the scientific task be finished? No, it would not. We would still need to decide, by some criterion of why it matters (a human, not a divine, concern), whether 0.85 is high enough to affirm the theory. No mechanical procedure can relieve us of this responsibility. Nor is it a decision that should be made privately, as a matter of "mere opinion." It is the most important scientific decision, and it should be made out in the open. The test of significance doesn't make it.

## II. A History of Consciousness

The overuse of statistical significance arises largely from its name. Surely, it insinuates, we serious scientists should be interested first of all in "significant" coefficients: the wise and good would not wish to waste time on trivialities. The appeal is part of the rhetoric of statistics (compare my book, 1985, ch. 2). The British inventors of statistics, as recipients of classical educations, were skillful in naming their ideas. As William Kruskal, a statistician of note, has argued:

Suppose that Sir R. A. Fisher—a master of public relations—had not taken over from ordinary English such evocative words as "sufficient," "efficient," and "consistent" and made them into precisely defined terms of statistical theory. He might, after all, have used

utterly dull terms for those properties of estimators, calling them characteristics A, B, and C.... Would his work have had the same smashing influence that it did? I think not, or at least not as rapidly. [1978, p. 98]

As the words spread to less sophisticated research workers, the task of undoing the rhetorical damage commenced. The earliest paper making the point of the present one was written in 1919 by, alarmingly, Edwin Boring. Attacks on the mechanical use of significance became commonplace early in statistical education. By 1939, for example, a *Statistical Dictionary of Terms and Symbols* of no great intellectual pretensions was putting the point utterly plainly: "A significant difference is not necessarily large, since, in large samples, even a small difference may prove to be a significant difference. Further, the existence of a significant difference may or may not be of practical significance" (A. K. Kurtz and H. A. Edgerton, 1939, article "Significant Difference"). M. G. Kendall and A. Stuart's *Advanced Theory of Statistics* explicitly recognized the mischief in the rhetoric, recommending the phrase "size of the test" in preference to "significance level" (1951, p. 163n); the sociometricians Denton Morrison and Ramon Henkel (whose book *The Significance Test Controversy*, 1970, is the best reading on the subject) suggest that "significance test" be replaced by the less portentous "sample error decision procedure" (p. 198).

In the 1930's, Jerzy Neyman and E. S. Pearson, and then more explicitly Abraham Wald, argued that actual statistical decisions should depend on substantive, not merely statistical, significance. As Wald wrote in 1939:

The question as to how the form of the weight [i.e., loss] function  $W(\theta, \omega)$  should be determined, is not a mathematical or statistical one. The statistician who wants to test certain hypotheses must first determine the relative importance of all possible errors,

which will entirely depend on the special purposes of his investigation. [p. 302]

Economists have largely ignored Wald's economical logic, with the result that few textbooks in econometrics mention that the goodness or badness of a hypothesis cannot be decided on merely statistical grounds.

### III. The Practice of Economists

It is not easy, then, to justify the use of probabilistic models to answer nonprobabilistic questions. One might retort that good economists do not make such mistakes. But they do, as may be seen from their best practice, in this *Review*. From the fifty full-length papers using regression analysis in the four regular issues of 1981, 1982, and 1983, I took a sample of ten for close scrutiny. Since the purpose is to criticize a socially accepted practice, not to embarrass individual writers, I shall withhold the names here (a larger version of the paper contains them, and a still larger one will examine all fifty).
